indicated by connections between the switch terminals. The usual off position then becomes the "operate" position of the bridge. The other two positions are indicated as "check" and "charge" positions. The "check" circuit allows the zero of the detector to be checked and adjusted, at the same time removing the bridge voltage from the measuring arm *P*. The "charge" circuit also allows the zero of the detector to be checked while leaving the bridge voltage across the measuring arm *P* so that measurements may be made from time to time with a continuous application of voltage to the measuring cell. This arrangement allows the time-decay of conductance to be measured from one to two minutes after the application of voltage, that time being necessary for the detector circuit and galvanometer to attain a steady state.

The 0.01, 0.1, and 1 megohm standards are accurate to 0.1 per cent and by connecting the proper open switch terminals of arm *N* to the low terminal of arm *P* it was possible to calibrate the 1,000, 100, and 10-megohm resistors to better than 0.3 per cent. The sensitivity of the detector is such that in measuring a resistance of the order of 10^{14} ohms the error is less than five per cent with about five volts applied. The detector sensitivity limits the value to which the bridge voltage may be reduced; this value also depending upon the resistance value of the oil-filled cell being measured. By the use of a more sensitive detector arrangement the accuracy of the bridge can be increased and the bridge voltage further reduced. It is obvious that the uses of this bridge are not limited to conductance measurements, but that it may also be used to measure almost any type of a high resistance up to 10^{15} ohms.

Guard Circuit

In this bridge the necessity for a conventional shield circuit is circumvented by the use of arms *A* and *B* as a shield circuit. The error in this method is negligible when measuring oils of low conductance and high resistance. However, as the value of the resistance between the guard ring and the low electrode of the cell decreases to approach the value of the resistance in arm *B*, the effective value of *B* will be accordingly affected. Since the resistance between the guard ring and the low electrode acts as a shunt around arm *B*, it is necessary in order to keep the error in arm *B* to less than 0.1 per cent that the value of this shunting resistance should be 1,000 times *B* or about 1,000 megohms. The resistance between the guard ring and the measuring electrode, which shunts around the detector, does not affect the accuracy of the bridge but may affect the sensitivity of the detector. Since the cell used in this work (figure 2) is so designed that the respective resistances between the guard ring and the measuring electrode and the guard ring and the low electrode are approximately the same as the resistance between the measuring and low electrodes, this guard circuit is quite satisfactory, and has the advantage of allowing measurements to be made rapidly. If it were desired it would be a comparatively simple matter to install a conventional shield circuit in the bridge.

Experimental Results

Two methods were chosen to show the value of low-voltage d-c measurements on electrical insulating oils. First, the change of d-c conductance with time was measured at various voltages and second, d-c measurements were compared with a-c measurements on the same oil sample. Through an inspection of these data, a few examples of which are presented here, a definite idea was obtained of the value of this type of a measurement.

Figure 4 shows the specific d-c conductances plotted against time for a heavy, dewaxed, solvent-refined, midcontinent oil[3] with bridge voltages of 20, 200, and 500 volts. It will be noted that with 20 volts per millimeter gradient (the cell spacing being 1.04 millimeters), a constant conductance was observed for a period of 15 minutes, while in the case of the higher potentials of 200 and 500 volts the conductance decreased rapidly with time from the initial two-minute reading. It is believed that these curves are thus an excellent confirmation of the theory expressed above, namely, that by reducing the potential gradient in the oil the velocity of the ions would be so reduced that the constant

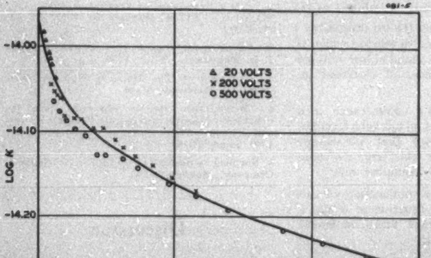

Figure 5. Logarithm of specific conductance versus (voltage × time)

conductance of region B in figure 1 would exist for a much longer period of time. This interpretation of these curves would lead us to conclude that low-voltage measurements of this type do measure the true d-c conductance of electrical insulating oils.

Figure 5 shows a plot of the logarithm of the specific d-c conductance (κ) of the same oil against the product of voltage (V) and time (t). For all three voltages the points fall along the same curve, showing that the conductance change depends upon the quantity of electricity passed through the oil. If we assume that this decrease in conductivity is due entirely to the discharge of ions at the electrodes, we can, by the use of certain other assumptions calculate the mobilities of the ions involved from the slope ($d \log_e \kappa/d(Vt)$) of a curve such as shown in figure 5. For this oil mobilities varying from 8×10^{-10} to 3×10^{-8} cm^2 sec^{-1} volt^{-1} were thus obtained. These mobilities are of a reasonable order of magnitude, and these investigations are being continued.

Using the power-factor bridge[4] which has been developed in this laboratory, power-factor measurements were made on the same oil samples on which d-c measurements were made. By the use of the formula

$$\kappa=0.556\times10^{-12}\nu \tan \delta C/C_0$$

where δ is the loss angle, C and C_0 are the capacitances of the cell with oil and air respectively as dielectrics, and ν is the frequency in cycles per second at which the measurement is being made, specific a-c conductances were computed for purposes of comparison with d-c values. Table I gives the specific conductances of a low-viscosity distillation cut of a midcontinent crude[5] at various stages of oxidation at 65 (±1) degrees centigrade. On inspection of these data it will be seen that there is, in general, good agreement between the d-c and a-c values, the average deviation from the mean being about five per cent. The deviations were thought to be due largely to fluctuations in temperature, and these fluctuations will be reduced in subsequent work. However, it is considered that these data do definitely show that the a-c losses are, in the case of this oil, wholly due to the same type of a loss which gives a d-c conductance and which is generally considered to be the result of ionic conductance. This type of a comparison is now being made on other oils that are being investigated in this laboratory. Since by this type of a comparison, low-voltage d-c measurements do account for all of the a-c losses it may again be concluded that the low-voltage measurements herein described do measure the true d-c conductances of electrical insulating oils.

Summary

1. Apparatus has been developed which is suitable for the measurement at low voltages of the d-c conductances of electrical insulating oils.

2. The change of d-c conductance with time of a highly refined oil has been found to substantiate the theory that low-voltage methods do measure the true d-c conductance of electrical insulating oils.

3. The change in the conductance of this oil is shown to be a function of $V\times t$, V being the applied voltage, and t the length of time of application.

4. D-c measurements have been compared with a-c measurements on a low-viscosity oil and low-voltage d-c measurements have been shown to account for all of the a-c loss in the oil thereby again leading to the conclusion that the low-voltage methods developed in this paper do measure the true d-c conductance of electrical insulating oils.

Rapid-Recording A-C Bridge

W. MIKELSON
ASSOCIATE AIEE

H. W. BOUSMAN
MEMBER AIEE

THIS paper describes a rapid automatic recording a-c bridge for continuously recording the power factor and capacitance during life runs or short-time tests on cables, capacitors, and insulating materials at a frequency of 60 cycles per second.

During the manufacture of electrical insulating structures and also during such extreme variations in conditions as occur on accelerated life tests, changes occur in the dielectric power factor and in the capacitance which are not fully reversible. A full record of such changes may be expected to contribute toward an understanding of the factors leading to failure under operating conditions. Data of this type in the past, generally were obtained manually, plotting point-by-point measurements made on a manual bridge. It is often desirable to obtain records of rapid changes which occur faster than can be recorded by this method. The automatic bridge described here rapidly records any change in the test specimen and is capable of operation 24 hours a day without attention. A photograph of the complete equipment is shown in figure 1.

A block diagram of the equipment is shown in figure 2. Referring to this diagram, a Schering bridge is used to measure capacitance and power factor. The voltage across the detector diagonal of the bridge, indicating bridge unbalance, is amplified and impressed upon circuits sensitive to components of the unbalance voltage produced by capacitance change and power-factor change respectively in the test specimen. These phase-sensitive circuits, called "phase selectors," control two thyratron circuits which supply power to two motors. The motors are coupled to adjustable circuit elements in the arms of the Schering bridge so that the unbalance voltage is reduced to zero and the motors are de-energized. Thus, the bridge is automatically balanced for the new values of capacitance and power factor which the test specimen has assumed. The time required for this operation is about one second. To prevent motor travel beyond the balance point because of the inertia of the motor arma-

Paper 40-82, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted November 16, 1939; made available for preprinting May 7, 1940.

W. MIKELSON and H. W. BOUSMAN are in the general engineering laboratory of the General Electric Company, Schenectady, N. Y.

tures and the associated moving parts, an antihunting feature is built into the equipment.

The new positions assumed by the circuit elements are indicated on the capacitance and the power-factor recorders, the pens of which are electrically coupled to, and move in unison with, the shafts of the bridge-circuit elements. The scales are marked directly in capacitance increase and in power factor. The recording Schering bridge consists of the following units:

Figure 1. Rapid-recording a-c bridge

1. Schering bridge
2. Voltage amplifier
3. Phase selectors
4. Thyratron circuits and motors
5. Antihunting circuits
6. Recorders

The following is a brief discussion of the circuits and the principle of operation of each unit.

Schering Bridge

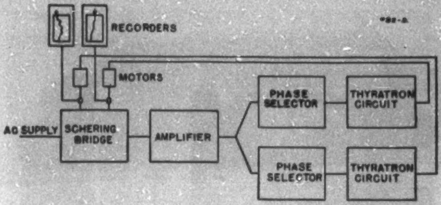

Figure 2. Block diagram of complete automatic bridge

The Schering bridge is the conventional one shown in figure 3. A fixed resistor R_4 is shunted by an adjustable capacitor, and connected in series with a high-voltage standard capacitor, C_1. R_3 is a manually adjustable resistor in series with the specimen capacitor. Power-factor balance is obtained by setting the adjustable capacitor for balance. Capacitance change in the specimen is measured by adjusting a tap on a slide-wire resistor shunting the R_3 resistor until bridge balance is obtained. Guard circuit potential is adjusted by setting the resistor *F* to the point which allows push button *B* to be operated with no change in the "capacitance change" balance.

A choice of several fixed resistance values at R_4 and a manually-operated step capacitor in parallel with the adjustable capacitor provide a means for selecting a power-factor range suited to the specimen tested. Range widths on the present bridge are 0.01, 0.02, and 0.05 tangent loss angle, which is approximately equal to the power factor or the sine of the loss angle. By use of the step capacitor, tangent loss angle as large as 0.3 may be measured, in which case the range covered by the recorder chart will be 0.25 to 0.30 tangent loss angle. Capacitance changes for full chart width deflection are $2^{1}/_{2}$, 10, 25, and 100 per cent. When used with a 100-micromicrofarad standard capacitor, capacitances from 50 to 10,000 micromicrofarads can be measured. Larger capacitances may be measured with the aid of external shunts. A photograph of the motor-operated Schering bridge unit is shown in figure 4.

It is possible to test several specimens in succession by providing an adjustable resistor in series with each and a time switch for connecting the slide wire at R_3 successively to each.

Voltage Amplifier

The function of the amplifier is to increase the feeble unbalance signal appearing at the output of the bridge when unbalance occurs, so that sufficient voltage is available to operate the phase-selector circuits. With a few exceptions, it is a conventional three-stage amplifier with resistance and capacitance interstage coupling and transformer input, as shown in figure 5. A photograph of the amplifier and phase-selector unit is shown in figure 6.

For proper operation of the phase-selective circuits which follow the amplifier, the phase shift in the amplifier must be either zero or an integral multiple of 90 degrees and the output voltage must be relatively free from harmonics. Control of both is obtained by the insertion of resistance-capacitance attenuators *R,C* between stages. The need for these effects is explained later.

Series resistances are inserted in the leads to the grids of the second and third stages to minimize parasitic phase shifts. To minimize changes in amplifier performance produced by changes in tube characteristics if the tubes overload, all plate load resistances are chosen low. Amplifier sensitivity is controlled manually by potentiometer resistors in the grids of the first two stages.

Phase Selectors

The function of the phase selectors is to separate the voltage components of bridge unbalance produced by capacitance and power-factor changes in the test specimen. The amplified bridge unbalance voltage is simultaneously applied to both phase selectors, but a capacitance unbalance causes one phase selector to function while a power-factor unbalance actuates the other. If both quantities change in the test specimen, both respond. The amplifier and both phase selectors are mounted on one panel as shown in figure 6. For purposes of clarity, only one has been shown in the circuit diagram in figure 7.

The phase selector operates by comparing the phase and magnitude of the amplified bridge unbalance voltage applied to *T*, with the phase of a reference voltage E_R which is the a-c supply voltage used for the Schering bridge. For this reason, it is important to control the phase shift in the amplifier as noted before.

Assume that a change has taken place such that the signal to the grid transformer *T* is in phase with the reference voltage E_R which is applied to the plates. Under this condition, for a given signal voltage the phase selector gives its greatest output. For the instantaneous polarities of plate and grid voltage indicated in the diagram, tube 1 passes current during the half cycle that this condition is maintained. During the next half cycle, tube 2 passes current. Thus, a pulsating direct current passes through the common load resistor R_1, producing an average direct voltage across the output terminals leading to the thyratron circuit, the magnitude of which is proportional to the magnitude of the input signal to *T*. If the signal voltage is 180 degrees reversed, tubes 3 and 4 pass current through R_2, producing a voltage of opposite average d-c polarity across the output terminals. However, if the signal is in quadrature with the reference voltage, all tubes pass current during a portion of the cycle and the average direct voltage across the output terminals is zero. Under this condition, the other phase-selector circuit is actuated. The phase selector not described is identical except a 90-degree phase-shifting network is inserted ahead of the signal input transformer *T*.

The phase selector is not affected immediately by harmonics of the applied voltage, but it is necessary partially to filter out the harmonics present in the bridge unbalance voltage to avoid overloading the amplifier with these harmonic voltages, thereby decreasing the response to the fundamental bridge unbalance voltage.

Thyratron Circuits and Motors

The function of the thyratron circuits is to supply power to the balancing motors at a rate dependent upon the magnitude of the d-c output of the phase selectors. Both thyratron circuits are contained on one panel shown in the photograph in figure 8. The motors are mounted on the Schering bridge panel shown in figure 4.

A diagram of one of the thyratron circuits is shown in figure 9. The motor is series wound with a divided field winding, each field winding being connected in the plate circuit of a thyratron tube. The grid bias and plate-supply voltages,

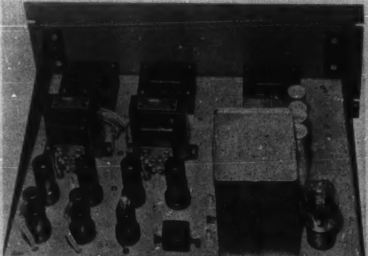

Figure 6. Rapid-recording a-c bridge; amplifier and phase-selector unit

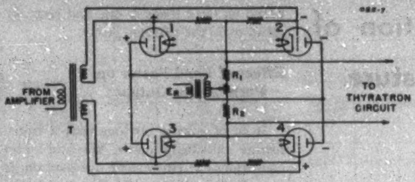

Figure 7. Circuit diagram of phase-selector unit

e_g and e_p respectively, are obtained from the 60-cycle a-c power supply. With d-c excitation on the grids, the tube with a positive grid fires or starts to pass current during each positive half cycle of the a-c supply voltage on its plate. This current persists until the end of the half cycle. If the d-c grid excitation changes polarity, the other tube fires, sending current through the other field winding and causing the motor to reverse direction. Speed of rotation is controlled as follows. For a high value of d-c grid excitation, the tube passes current during the full half cycle. For low excitation, the current impulse is shorter because the tube fires later in the half cycle. Hence, the average current through the motor becomes less and the motor runs more slowly.

The operation of the thyratron tube in this circuit can be explained as follows. The capacitor C_4 in the grid-bias transformer T_3 produces a constant phase shift in the alternating bias voltage e_g which lags the plate voltage e_p by about 90 degrees as shown in figure 10. Under this condition, the grid is at no time sufficiently positive to cause the tube to fire. With a slight positive d-c grid excitation superimposed upon the a-c bias, e_g is raised high enough to cause the tube to fire during the latter part of the positive half cycle of e_p. With increased d-c excitation, e_g is raised still higher so that the lowest point in this curve becomes sufficiently positive to cause the tube to fire, and the tube passes current for the full half cycle. Thus, regulated control of motor speed, depending upon the magnitude of the grid excitation voltage, is obtained.

Figure 8. Rapid-recording a-c bridge; thyratron unit

Antihunting Circuit

The function of this circuit is to prevent hunting produced when the inertia of the motor and associated rotating parts cause the motor to follow through or overshoot the correct position when the bridge balance is reached, thereby unbalancing the bridge in the reverse direction and setting up an oscillating condition.

A resistor R_8 and capacitor C_8 shown in figure 9 are inserted in the signal input lead to the thyratron circuit. These build up a temporary d-c potential in series with the signal voltage and opposite in polarity. This reduces the effective voltage at the thyratron grids and causes it to drop to zero slightly before the bridge has actually reached balance. The motor, by virtue of its inertia, then tends to coast to the proper position. Should the motor not stop at the correct position, the antihunting voltage quickly drops to zero, the signal voltage again takes effect, and the motor receives an additional impulse which finishes the balancing operation.

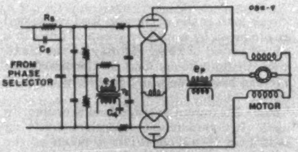

Figure 9. Circuit diagram of thyratron unit

Recorders

The function of the two recorders is to follow the position of the capacitance and power-factor balancing elements in the Schering bridge, thereby recording the capacitance and power factor of the test specimen as a function of time.

Each recorder has a separately excited ratio-type instrument movement excited from the a-c supply line through a resistance potentiometer mechanically coupled to the shaft of the balancing element in the bridge. The line voltage can vary as much as 20 per cent without affecting the indication. Chart speeds of one inch per minute and one inch per hour are provided.

Switches for changing bridge range, giving an alarm, or discontinuing the test may be located on the balancing elements to handle specimen changes larger than anticipated.

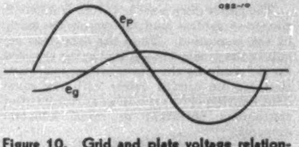

Figure 10. Grid and plate voltage relationship; thyratron unit

Summary

A power-factor and capacitance bridge capable of unattended recording has been described. Changes in the specimen may be fully recorded within one second of their occurrence.

The bridge may be used in connection with life tests, during treating processes, and for recording tests on large numbers of nominally identical structures, in the process of production.

The automatic control circuits described in this paper are not limited only to application to the Schering bridge, but may be used for automatic balancing of practically any other type of a-c bridge as well.

Effect of Load Factor on Operation of Power Transformers by Temperature

V. M. MONTSINGER
FELLOW AIEE

Synopsis: The practice of loading transformers by temperature is growing among operators who desire to take advantage of the additional capacity offered by this method of loading. The standards now recognize continuous overloads in cool ambients and short-time overloads under recurrent and emergency conditions.

The paper discusses the effects of different shapes of system load factors on the aging of the insulation. Then the ones that result in the greatest amount of aging are used for determining the permissible peak loads that can be carried safely with the same deterioration of its insulation as results from continuous operation at rated kilovolt-amperes.

A rational method of calculating the hot-spot temperature is shown by means of examples using a general average "time constant". The hot-spot temperature curve is then integrated to compare the aging with a given constant temperature.

From these results it is concluded that a normal power transformer can be overloaded 3 per cent for each 10 per cent that the system load factor is below 100 per cent. That is, for a 50 per cent load factor the permissible peak load is 15 per cent over the transformer rating in a standard ambient. For low ambients where 1 per cent overload for each degree that the ambient is below 30 degrees is now permitted, the permissible peak loads will vary depending on ambient and on load factor. By combining the 3 per cent rule for load factor and 1 per cent rule for ambient, proposed loading curves are shown for different load factors and different ambients.

SEVERAL papers have been written[1,3,5] on the operation of transformers by temperature during the past several years. As a result of these activities, the American Standards Association sectional committee on transformers, *C*-57 has published "Guides for Operation of Transformers" as an appendix to the proposed American standards for transformers, regulators, and reactors.

These guides give permissible overloads under the following conditions: (1) continuous overloads in cool ambients, (2) short-time overloads under recurrent conditions, and (3) short-time overloads under emergency conditions. These short-time overloads apply to transformers irrespective of the system load factors, and are limited to a few hours duration.

There are conditions under which the maximum load may last for times longer than those permitted for the overloads given in the guides, and where it is safe to carry some overload. It is primarily for this condition that this paper is presented.

Load Factor—Definition

The ASA definition for load factor (35.10.125) is as follows:

"Load factor is the ratio of the average load over a designated period to the peak load occurring in that period".

The ASA definition of peak load (35.10.135) is:

"Peak load is the maximum load consumed or produced by a unit or group of units in a stated period of time. It may be the maximum instantaneous load or the maximum average load over a designated interval of time".

"*Note:* Maximum average load is ordinarily used. In commercial transactions involving peak load (peak power) it is taken as the average load (power) during a time interval of specified duration occurring within a given period of time, that time interval being selected during which the average power is greatest".

Load factor as used in this paper refers to the load on the transformer bank under consideration. It is to be noted that load factor as so defined is to be distinguished from the ratio of the average load to the transformer rating, as this latter ratio is, by ASA definition, "capacity factor".

Very few power transformers operate at 100 per cent load factor, the majority of load factors being in the order of 50 to 70 per cent.

There are in general three types of loads, industrial, residential, and combined industrial and residential, all of which generally have load factors well below 100 per cent. Figures 1, 2, and 3 are good illustrations of such loads. These load factors are 51.5 per cent, 55 per cent, and 60.5 per cent respectively, based on peak loads of one-half hour, instead of on the extreme peaks.

Effect of Load Factor on Permissible Output

It is, of course, obvious that a transformer operating under low-load-factor conditions can carry some overload under peak load conditions with the same degree of aging of its insulation as one carrying rated load continuously. The problem is to determine the amount of overload that will give the same aging, for different load factors. To do this requires: (1) determination of the hottest-spot temperature during one complete 24-hour period, and (2) integration of the hottest-spot temperature curve during the 24-hour period, to obtain the amount of aging of the insulation. When an overload is found (by trial) to cause the same amount of aging as occurs when the transformer is carrying rated load for 24 hours, this represents the permissible overload for that particular kind of load curve.

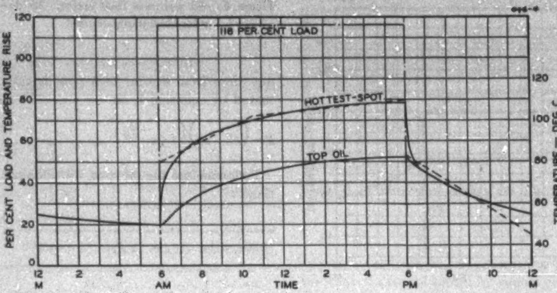

Figure 4. 50 per cent load factor composed of industrial load for 12 hours during 24-hour period

24-hour average load = 58 per cent; 30 degrees centigrade ambient

The permissible overload for a given load factor varies over a wide range, depending on the shape of the load curve. For example: a 50 per cent load factor in which 100 per cent load is carried 50 per cent of the time, with no load on the remainder of the time (figure 4) will permit a minimum overload rating, whereas a 50 per cent load factor in which partial load is carried most of the time and a peak load is carried the rest of the time (figure 7) will permit a greater overload rating. The first case might correspond to an industrial 50 per cent load factor condition requiring power during the day, only, and the second case, might correspond to a condition where, during the late evening hours, a heavy residential peak load is superimposed on a light 24-hour load.

Calculation of Hottest-Spot Temperature

The hottest-spot temperatures are calculated in two stages. First, the top-oil temperature rise is obtained, and then the hottest-spot rise over the oil is determined and added to the top-oil rise. The most difficult part is the calculation of the oil temperature under varying load conditions. When this is done, the rest is easy, since the winding rise over the oil becomes constant in 20 to 30 minutes and can be taken directly from a curve of ultimate rise versus load, and added to the oil rise.

For the particular case under consideration the following assumptions are made, in calculating the hottest-spot temperatures.

1. The ratio of losses at rated load is 2:1 (2 copper, 1 iron).
2. The ultimate top-oil rise at rated load is 45 degrees centigrade.
3. The hottest-spot temperature rise over the top oil is 20 degrees centigrade (10 degrees average rise +10 degrees hot-spot rise over average rise) at rated load, and varies as the load raised to the 1.6 power.[1]
4. The no-load ultimate oil rise is 19 degrees centigrade. (The exact value based on 2:1 ratio of losses at rated load and temperature rise varying as 0.8 power is 18.7 degrees centigrade.)
5. The ultimate oil rise varies as the 0.8 power[1] of the losses.
6. The time constant corresponds to that for the average single-phase power transformer ranging in size from 1,000 to 33,333 kva. Table I.
7. One hundred per cent excitation voltage is on at all times. The time constant is, therefore, based on the copper losses only.
8. The load cycle selected is repeated from day to day such that the oil temperature is the same at the beginning and end of each 24-hour period.
9. A constant ambient temperature of 30 degrees centigrade is maintained.

Tests have shown[5,11] that the oil rise under transient conditions can be estimated quite closely by the exponential formula:

$$\theta_r = \theta_u\left(1-\epsilon^{-\frac{t}{B}}\right) \tag{1}$$

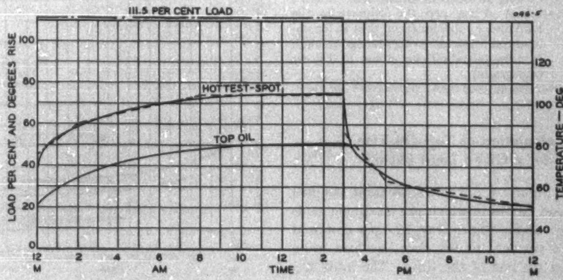
where

θ_r = temperature rise of oil at any time t
θ_u = ultimate oil rise
ϵ = 2.718
t = time in hours
B = time constant*
$= \dfrac{C \times \theta_u}{\text{loss at initial temperature}}$
C = thermal capacity of iron core, windings (copper) tank and oil
$= \dfrac{3.5 \times \text{pounds (core+copper+2/3 tank)} + 90G}{60}$
G = gallons oil (United States)

---

* The time constant is the time required to reach ultimate temperature rise, if all heat were stored in the transformer.

Figure 5. 62.5 per cent load factor; 30 degrees centigrade ambient



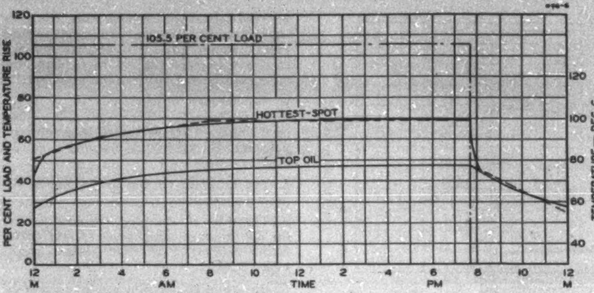


Figure 6. 82 per cent load factor, 30 degrees centigrade ambient

Only 2/3 of the tank is used because the lower third is comparatively cool, and 85.7 per cent (of 105*G* the correct value to use when the oil is at a uniform temperature) of the oil is used for the same reason.

In table I are some representative values of *B* for load (copper) losses only, taken at 110 per cent load. One hundred and ten per cent load was chosen for the reason that the overload periods exert the greatest effect on the life of the insulation, and 110 per cent load is a general average value used for the various load factors.

The average of the values of *B* in the table is 3.38. A general average value of 3.33 appears to be a reasonable one to use. It is proper to point out, however, that *B* varies to some extent for different oil rises for the reason that the oil rise is not proportional to the losses but varies as the 0.8 power of the losses. Tests show,[8] however, that results close enough for practical purposes are obtained by using an average value of *B* for the oil rises under consideration.

Equation 1 applies to oil-temperature rises. When the oil temperature is cooling down, the following equation applies:

$$\theta_c=\theta_i\left(1-\epsilon^{-\frac{t}{B}}\right) \qquad (2)$$

Where

θ_c = cooling in degrees during time period t
θ_i = initial oil rise over the ultimate for the load under consideration (that is, for no-load condition following some given load, θ_i is the initial oil rise minus 19 degrees centigrade)
t = time in hours
$B = 3.33$

Calculation of Top-Oil Rise for a Given Load Factor

Figures 4, 5, and 6 show three assumed load curves in which the maximum loads are on for 50 per cent, 62.5 per cent, and 82 per cent of the time—no load being on the rest of the time. The loads are, therefore, 50, 62.5, and 82 per cent respectively. Figure 7 shows load curve with a 50 per cent load factor, made up of a 51.5 per cent load for 19 hours, and 140 per cent load for 5 hours representing a peak residential overload from 5 to 10 p.m.

As an illustrative case, the top-oil rise will be calculated for the 50 per cent load factor, figure 4.

It was found by trial that the oil rise is 25 degrees at the beginning and end of the 24-hour period. This gives a starting point of 25 degrees centigrade rise at 12 midnight.

From 12 to 6 a.m., the oil is cooling down. Using equation 2 we have (when $t=6$ and the ultimate no-load oil temperature rise is 19 degrees centigrade)

$$\theta_c=\left(25-19\right)\left(1-\epsilon^{-\frac{6}{3.33}}\right)=5.0 \text{ degrees centigrade}$$

Therefore, at 6 a.m. the oil rise has dropped from 25 to 20 degrees centigrade.

At 6 a.m. 116 per cent load comes on and the oil temperature starts to rise. The ultimate oil rise for 116 per cent load is 53 degrees centigrade. The oil rise at any time from 6 a.m. to 6 p.m. is estimated by equation 1, or

$$\theta_r=\left(53-20\right)\left(1-\epsilon^{-\frac{t}{3.33}}\right)$$

Following are the oil rises, for different times t

Time	7 a.m.	10 a.m.	2 p.m.	6 p.m.
t=	1	4	8	12
θ_r=	8.6	23	30	32.0 over 20 degrees rise (starting at 6 a.m.)

From 6 p.m. to 12 midnight, the oil temperature again decreases:

$$\theta_u=(52.0-19)\left(1-\epsilon^{-\frac{6}{3.33}}\right)=27.0 \text{ degrees}$$

or $52.0-27=25.0$ degrees centigrade rise at 12 midnight

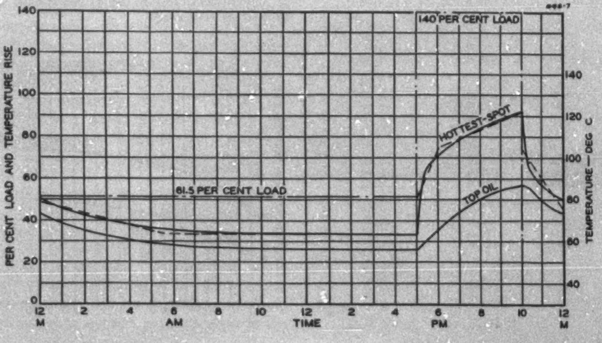
Adding 30 degrees centigrade ambient to the above values, we obtain the top-oil temperature as shown in figure 4.

The next step is to add the winding hottest-spot to the top-oil temperature curve shown in figure 4. The ultimate winding hottest-spot rises over the oil versus load are shown in figure 8, assuming 20 degrees rise at rated load.

The hottest-spot curve figure 4 is divided into trapezoids (dashed lines), for the purpose of integrating the area to determine the aging during a 24-hour period.

Figure 7. 50 per cent load factor, composed of light industrial and peak residential load

24-hour average load = 70 per cent; 30 degrees centigrade ambient



As shown in a previous paper,[10] the aging may be computed by the following equations:

For a constant temperature

$$A = t\epsilon^{kT} \qquad (3)$$

where

A = aging units
ϵ = 2.718
T = temperature degrees centigrade
k = 0.0865—which doubles the aging for each 8-degree-centigrade increase in temperature

For a trapezoid in which the two unequal sides represent temperature

$$A = t\left[\frac{\epsilon^{kT_2} - \epsilon^{kT_1}}{k(T_2 - T_1)}\right] \qquad (4)$$

where

T_2 = the maximum temperature degrees centigrade
T_1 = the minimum temperature degrees centigrade

As previously stated, the load-cycle conditions have been selected such that the aging will be the same as that under continuous rated load conditions. For a 24-hour period, the aging at 95 degrees centigrade (55 rise by resistance+10 degrees hottest-spot+30 degrees ambient) is by equation 3

$$A = 24\epsilon^{0.0865\times 95}\ 87{,}500 \text{ units}$$

Integrating the hottest-spot (dashed) curve in figure 4, the aging by equation 4 is

$$A_1 = 6\left[\frac{\epsilon^{0.0865\times 55.0} - \epsilon^{0.0865\times 50}}{0.0865(55.0-50)}\right] = 570$$

$$A_2 = 4.5\left[\frac{\epsilon^{0.0865\times 102} - \epsilon^{0.0865\times 80}}{0.0865(102-80)}\right] = 13{,}650$$

$$A_3 = 7.5\left[\frac{\epsilon^{0.0865\times 110} - \epsilon^{0.0865\times 102}}{0.0865(110-102)}\right] = 70{,}000$$

$$A_4 = 6\left[\frac{\epsilon^{0.0865\times 83} - \epsilon^{0.0865\times 45}}{0.0865(83-45)}\right] = \underline{2{,}320}$$

$$\text{Total} \quad 86{,}540 \text{ units}$$

The figure 86,540 is close enough to 87,500 units since a change of one degree centigrade affects the aging approximately 12.5 per cent—based on the rate of aging doubling for each eight-degree-centigrade increase in temperature.

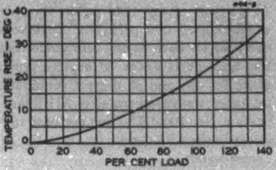


Figure 8. Hottest-spot winding rise over top oil

It is well to point out that "integration by parts" of the hot-spot temperature curve gives approximately correct results. That is, if in figure 4 the "time" is divided into one hour and one-half hour intervals (depending on the rate of change of temperature) and the average of these time interval hot-spot values is used for T in equation 3, the total aging units obtained are 86,980 which are within 0.5 per cent of those obtained by equation 4. In fact, when the hot-spot curve is quite irregular, the method of "integration by parts" is simpler and probably more accurate.

The aging of figure 7 is by equations 3 and 4:

$$A_1 = 5.5\left[\frac{\epsilon^{0.0865\times 79} - \epsilon^{0.0865\times 64}}{0.0865(79-64)}\right] = 2{,}800$$

$$A_2 = 11.5\times\epsilon^{0.0865\times 64} = 2{,}890$$

$$A_3 = 1\left[\frac{\epsilon^{0.0865\times 105} - \epsilon^{0.0865\times 80}}{0.0865(105-80)}\right] = 3{,}570$$

$$A_4 = 4\left[\frac{\epsilon^{0.0865\times 121.5} - \epsilon^{0.0865\times 105}}{0.0865(121.5-105)}\right] = 75{,}000$$

$$A_5 = 2\left[\frac{\epsilon^{0.0865\times 105} - \epsilon^{0.0865\times 75}}{0.0865(105-75)}\right] = \underline{6{,}400}$$

$$\text{Total} \quad 90{,}660 \text{ units}$$

Again, 90,660 units is close enough to 87,500 units—the aging at 95 degrees centigrade for 24 hours.

From the above results, it can be seen that the permissible overload for a 50 per cent load factor ranges from 16 per cent (figure 4) to 40 per cent (figure 7) depending on the character of the overload.* With shorter than five-hour peak loads imposed on partial load conditions, the permissible overload would be greater than 40 per cent. For a one or two-hour peak load, the permissible overload, considered only from the standpoint of aging, might be as high as 80 to 100 per cent. These heavy overloads might not be safe. In the first place, there are often limits other than aging of the insulation, such as overheating of lead joints (when soldered) and ratio-adjuster contacts, regulation, etc. In the second place, it has been shown[11] that when cellulose is maintained at temperatures above approximately 120 degrees centigrade chemical deterioration becomes an important factor.

Table II. Permissible Loads for Self-Cooled Transformers (Per Cent of Rated Capacity)

Per Cent Load Factor	Ambient Temperature (Deg C) 0	5	10	15	20	25	30
50	145	140	135	130	125	120	115
60	142	137	132	127	122	117	112
70	139	134	129	124	119	114	109
80	136	131	126	121	116	111	106
90	133	128	123	118	113	108	103
100	130	125	120	115	110	105	100

Under a condition of this kind the short-time heavy overload should be limited to the time specified in the ASA guides. For example if, when following 50 per cent load, the overload was 1.4 times the rated load current the time should be limited to approximately 25 minutes for recurrent conditions and to approximately 100 minutes for emergency conditions.

General rules for overloading transformers should be safe for the worst condition, as one is not sure of the conditions under which these rules will be used.

An integration of the hottest-spot temperature curves shown in figures 5 and 6 gives maximum peak loads of 111.5 per cent with 62.5 per cent load factor and 105.5 per cent with 82 per cent load factor.

It is recognized that with water-cooled transformers the aging under low load factor might be more than for self-cooled transformers, because the oil temperature will respond more quickly to load changes. The difference, however, will not be very great since the faster oil cooling will partially compensate for the faster oil heating up.

The ASA recommended overloads as covered in the guides for operation of transformers, limits two-hour recurrent overloads to 10 per cent and 20 per cent, following full-load and no-load conditions respectively; also, emergency two-hour overloads are limited to 25 per cent and 40 per cent respectively.

The object of presenting the data in this paper is not to replace or supersede the ASA's recommendations which are

Table III. Permissible Loads for Water-Cooled Transformers (Per Cent Rated Capacity)

Per Cent Load Factor	Ambient Temperature (Deg C) 0	5	10	15	20	25
50	140	135	130	125	120	115
60	137	132	127	122	117	112
70	134	129	124	119	114	109
80	131	126	121	116	111	106
90	128	123	118	113	108	103
100	125	120	115	110	105	100

---

* For the load curves shown in figures 1, 2, and 3, the permissible overloads are in the order of 25 per cent to give the same aging as for continuous operation at rated loads. In other words, the rating of the transformers could be 80 per cent of the peak loads.

not directly coupled with load factor, but rather to show what is possible under different load-factor conditions, and (most important) to point out the limitations to the use of overloads for various load factor conditions. Several utility engineers are calculating[7,8,9] the permissible overloads on distribution transformers under various conditions of service, and it is the hope that this paper will be of some benefit in these efforts.

We have seen that under the most severe conditions 16 per cent overload can be held on a transformer operating at its maximum load 50 per cent of the time, that is, 50 per cent load factor, figure 4. For 62.5 per cent and 82 per cent load factors shown in figures 5 and 6, 11.5 per cent and 5.5 per cent overloads respectively can be held.

Expressed in terms of load factor, we have:

Figure	Per Cent Load Factor	Per Cent Overload	Per Cent Overload for Each 10 Per Cent Reduction in Load Factor Below 100 Per Cent
4	50	16	3.2
5	62.5	11.5	3.07
6	82.0	5.5	3.05

It appears, therefore, that a safe rule would be to permit 3.0 per cent overload for each 10 per cent that the load factor is under 100 per cent. Approximately the same overload values were obtained in my 1930 AIEE paper,[1] although a different method of calculation was used.

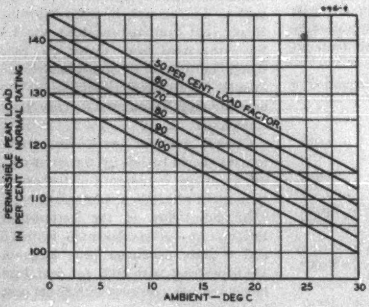

Figure 9 (left). Loading curves for self-cooled transformers

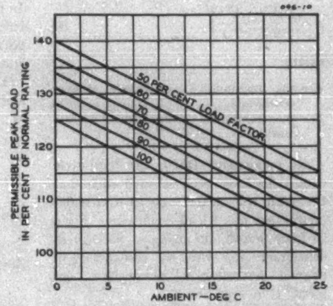

Figure 10 (right). Loading curves for water-cooled transformers

As a result of my 1930 paper, the rule which allows one per cent continuous overload for each degree centigrade that the ambient is under 30 degrees centigrade for air, and 25 degrees centigrade for water, was incorporated in AIEE publication No. 100. The one per cent rule is now in the ASA Guides for Operation of Transformers.

This information will permit taking advantage of both low load factor conditions and low ambient conditions, in cases where this seems advisable.

The proposal is to combine the three-per cent rule and the one-per cent rule which will give the permissible peak loads in per cent of normal rating for low load factors and low ambients as shown in tables 2 and 3 for self-cooled and water-cooled transformers respectively.

The values shown in tables II and III are plotted in curve form in figures 9 and 10. It is not intended that these overloads relating to load factors, be added to the short-time overloads already permitted by the ASA Guides for Operation of Transformers.

Future Work

To complete the work on loading power transformers by temperature, it is planned to present, at some future date, a paper showing how to convert any load cycle consisting of short-time high peak loads to the equivalent rectangular load cycle, and then limit its duration to the time given by the ASA guides.

Dead Points in Squirrel-Cage Motors

QUENTIN GRAHAM
ASSOCIATE AIEE

Synopsis: Certain squirrel-cage motors are known to have a wide variation in starting torque depending on the angular position of the rotor. In extreme cases the torque may be actually negative at certain positions making the motor entirely useless. Various names such as "dead points," "cogging," and "locking" torque have been used to describe this condition but no detailed study of its mechanism appears to be available.

An analysis of the causes of such behavior is presented here as one of several phenomena not covered by classical theory since they arise from the nonsinusoidal nature of the air-gap field. It is shown (1) that only with certain definite relations of slot numbers can dead points exist at all, and (2) that, given one of these vulnerable slot combinations, the amplitude of the torque variation moves over an extremely wide range as the coil span is changed. The effect of coil span is not merely that due to the numerical change of harmonic chord factor but is shown to be the result of changes of direction of the various component forces. Test results confirming the analysis are included. It now becomes possible to correlate a great many apparently divergent results and to avoid troublesome combinations in future designs.

THE simple elementary theory of squirrel-cage induction motors treats the air gap field as a pure sine wave. Based on this simplification the classical laws of motor performance have been developed. It is evident, however, that in most actual motors the flux field differs sufficiently from a simple sine wave to warrant a closer study of its shape if the performance is to be predicted accurately. For example, the following phenomena depend largely on the nonsinusoidal nature of the flux field.

1. Vibration and noise.
2. Stray load loss.
3. Parasitic torques resulting in
   - (*a*). **Asynchronous cusps in the torque curve.**
   - (*b*). **Synchronous locking at low speeds.**
   - (*c*). **Dead points or locking at zero speed.**

While all of these subjects have been investigated to some extent, the dead-point phenomenon has probably received the least attention and no detailed study of its mechanism is available, at least in the English language. The present paper attempts to fill this gap, offering an explanation of the cause of dead points and some test results that confirm the analysis. It is shown that only with certain definite relations of slot numbers is it possible for dead points or locking torque to exist at all, and, further that the magnitude of the locking torque varies over an extremely wide range as the coil span is changed. While it is admitted that exact quantitative results are difficult to predict, a basis for judging the probability of trouble is established.

Test Observations

A motor which exhibits dead points, or cogging, as it has sometimes been called, will be found to have the following characteristics. The locked-rotor torque varies with the angular position of the rotor, passing through a cycle for each rotor slot pitch. If the running torque is measured slightly above and slightly below zero speed, the torque is found to agree quite closely with the *average* locked value. The locked torque, therefore, is a constant amount plus a variable component which has positive and negative values dependent on the rotor position. The net locked torque may be entirely positive or it may be zero or even negative at certain positions of the rotor. In the latter case the motor is truly "dead" and will not start even without load. However, when the torque is all positive it is only the minimum value that is useful for starting a load. Figure 1 shows tested values of locked torque for a motor of this kind.

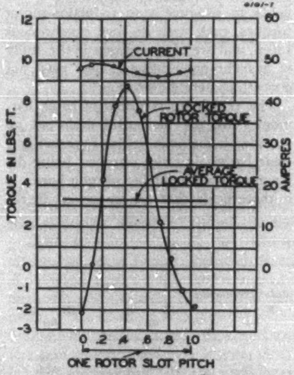

Figure 1. Typical test curve showing variation of locked rotor torque with rotor position

Motor had 24 stator slots, 18 rotor slots, 2 poles, 3 phases, 7/12-coil span, rotor-skewed one rotor-slot pitch

The variable component of torque is similar to the torque of a synchronous machine being dependent on the angular position of the rotor and passing through positive and negative half cycles. One is led therefore to search for a similar cause: two independent fields which are in synchronism at zero rotor speed and have distributions in space such as to give the required torque-angle characteristics. The following discussion shows that the necessary fields are present to fulfil just these requirements.

It has been observed further that motors having the same combination of stator and rotor slots may have widely different amounts of the variable torque component. Since most explanations of this phenomenon have been based heretofore on considerations of permeance variations, the observed results have appeared inconsistent. The analysis given here shows that these results can be explained.

Analysis

1. STATOR HARMONICS

As with many problems of this kind, it is sufficiently accurate to examine the harmonic fields of stator and rotor which result from the following assumptions:

(*a*). The slot currents are concentrated at points.

(*b*). The air gap permeance is uniform.

For integral-slot stator windings it is well known that the possible harmonics are:

$$n = 1 + MK \qquad (1)$$

where M is the number of phase belts per pair of poles, K is any positive or negative integer including zero. The algebraic sign of n shows the direction of travel with respect to the fundamental field. The velocity of each harmonic field is $1/n$th of the speed of the fundamental.

2. HARMONIC FIELDS OF SQUIRREL-CAGE ROTORS

A squirrel-cage winding carrying currents induced by the fundamental stator

---

Paper 40-101, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted November 8, 1939; made available for preprinting April 30, 1940.

QUENTIN GRAHAM is design engineer, motor engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

field sets up harmonic fields of the following order in addition to its fundamental field.

$$m = 1 + KS_2 \qquad (2)$$

where S_2 is the number of rotor bars per pair of poles, K is any integer. Usually the only fields having sufficient magnitude to be of importance are those obtained by letting K equal plus and minus one.

This, however, does not complete the list of rotor fields. In addition to currents in the rotor bars induced by the fundamental stator field, there are currents resulting from each of the other stator fields. For each separate current component flowing in the bars there are the following fields:

1. The nth, corresponding to the nth stator field which induced the current under consideration
2. The mth, where

$$m = n + KS_2 \qquad (3)$$

In this case it is usually necessary to consider only the one or two lowest values of m resulting from any given value of n.

3. COMPARISON OF ROTOR AND STATOR HARMONIC FIELDS

It is now possible to set down the harmonic fields of both members and compare them. For purposes of explanation it will be simpler to use an actual case and the one selected is a motor for which test data are available. The specifications are as follows:

Number of poles = 2
Number of stator slots = 24
Number of rotor slots = 18
Number of phase belts (total) = 6
Slots semiclosed for both members.

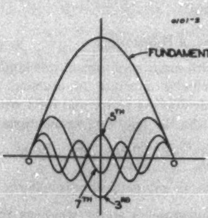

Figure 2. Relation of third, fifth, and seventh harmonics to the fundamental for a single coil

From these facts and the expressions for stator and rotor harmonics above, the orders of the various fields can be written as shown in table I.

The stator harmonics are simply those that occur in any three-phase motor having an integral-slot winding and the list could be carried out indefinitely. The first column under rotor harmonics is the series induced by the corresponding stator fields. These combine with the stator fields to produce true induction-motor torques, each with its own synchronous speed, and are of importance in the study of asynchronous cusps. They need not concern us here, however.

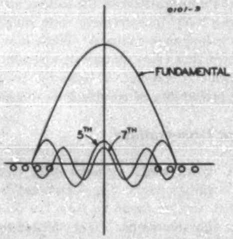

Figure 3. Relation of the fundamental, 5th and 7th harmonics for a three-phase winding with four slots per phase belt and full-pitch coils

The remaining columns of rotor harmonics are the incidental fields set up along with the main fields of column one, their harmonic order numbers being determined by the number of rotor bars. It is these fields that are important in the present study. It will be noticed that in setting up a secondary field with fundamental distribution we incidentally produce 17th and 19th harmonics which have the same signs as the 17th and 19th stator fields. Thus there is a pair of 17th harmonic fields moving backward at $^1/_{17}$th of synchronous speed but maintaining synchronism with each other while the rotor is at rest, and there is a pair of 19th harmonic fields going forward at $^1/_{19}$th speed under the same conditions. There are, then, steady torques produced by each of these pairs of fields but the direction and magnitude of these torques and their dependence on rotor position will have to be investigated further.

Table I

Stator Harmonics	Rotor Harmonics				
		(K = −1)	(K = +1)	(K = −2)	(K = +2)

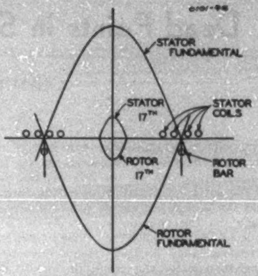

Figure 4a. Relation of 17th-harmonic waves of stator and rotor, for a particular coil span, with rotor in original position

Note: The 17th harmonic is drawn to an enlarged horizontal scale for clearness

Before going into these questions, however, we can take note of the fact that there are other such pairs of fields present. For each harmonic in the stator column, there is a corresponding harmonic in one or more of the rotor m columns.

4. THE PHASE RELATIONS BETWEEN THE HARMONICS

In order to proceed with an analysis of the torque components it is first necessary to establish phase relations between the various harmonic fields. Figure 2 shows three of the component fields of a single full-pitch coil in relation to the fundamental. If there are several symmetrical phases of one coil each, this picture also represents the relation between the combined harmonics of all phases at the particular instant when the current in the coil shown is a maximum. It will be noted that those harmonics in the series 1, 5, 9, 13, 17, etc., have positive maximums coinciding. Those in the series 3, 7, 11, 15, 19, etc., have their negative maximums coinciding with the positive

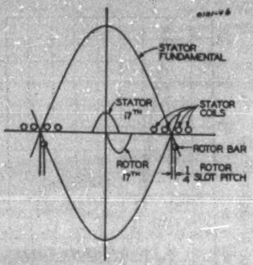

Figure 4b. Relation of stator and rotor 17th-harmonic waves after rotor has been moved one-fourth of a rotor-slot pitch

25	7	− 1.58	+0.96	+ 0.11	−0.96	+0.90	−0.24	−0.55	+0.96
Totals		26.70	28.15	16.30	0.31	5.79	6.42	4.55	0.31

For each coil span the number of turns of the winding is changed to keep a constant fundamental flux density.

Table applies to case of 24 stator slots. 18 rotor slots, 2 poles, 3 phase.

maximum of the fundamental. The significance of this point will be seen later.

In general there will be more than one coil per phase belt in the stator and the coils will not be full pitch, both factors having an effect on the relations found for a single coil. In the case of the example previously used having four coils per phase belt it is found that the vector addition of the harmonic components of all four coils gives phase relations as shown in figure 3. Some harmonics are now found to be reversed and others remain as they were for a single coil. The process of finding which ones reverse is discussed in more detail in appendix *B*.

Proceeding to the case of chorded windings, it is found for the sample motor that the various harmonics again either reverse or hold their positions depending on the coil throw as discussed in appendix *B*. For any given stator winding, therefore, it is possible to draw the relation between the fundamental and any or all harmonics for a particular instant.

Considering the rotor for a moment we see that it is equivalent to a winding with one coil per phase belt and so can be represented by figure 2 for any one component of current.

5. THE TORQUE CYCLE FOR ANY HARMONIC

The next step in the analysis is to place the rotor and stator fundamental waves together with about the same phase relation that they might be expected to have normally with the rotor locked. This would be nearly 180 degrees apart, the actual angle depending upon the power factor of the secondary circuit and the ratio between magnetizing current and total current. For our present purpose the exact angle is not very important and so for simplicity the two fundamental waves will be drawn 180 degrees apart (figure 4*a*). The zero points of the stator wave pass through the center of a phase belt and the zero points of the rotor wave pass through the center of two bars, a pole pitch apart. Under these conditions the 17th harmonic of the stator will bear a fixed relation to the 17th rotor harmonic as shown. An instant later the fundamental waves will have moved slightly in a positive direction while the 17th harmonics will have moved $^1/_{17}$th as far in a negative direction. Thus the picture represents only a particular instant. Since the two 17th waves do not change their positions relative to each other, however, the torque between them, which is zero in this case, is constant.

Suppose now that the rotor be turned through one-quarter of a rotor bar pitch and a new picture be drawn for the same instant in time as before. Figure 4*b* shows this and it will be seen that the two fundamental waves remain in the same relation to one another. This must occur since the secondary current is induced by the primary and the time relation of the current in the bars simply changes to accommodate the new bar position. The 17th stator wave remains as it was but the rotor 17th is shifted relative to the rotor fundamental. The amount of the change can be visualized by going back to figure 4*a* and considering the position of the two rotor waves after the elapse of sufficient time for the fundamental to have moved one-quarter of a rotor bar pitch. This distance is 5 degrees of the fundamental wave or 85 degrees if referred to the harmonic wave length. During this interval the 17th wave will have moved 5 degrees of its own wave length in the opposite direction. The relative movement is thus 90 degrees. A change in rotor position of one-fourth of a bar pitch has therefore resulted in a change in phase relation of the stator and rotor 17th harmonic waves of 90 degrees. In this new position there is a torque exerted between the two fields tending to bring them in line with one another. By continuing the process of shifting the rotor slightly it can be seen that when a shift of one complete bar pitch has been made the relative position of the harmonic fields will have gone through a full cycle and the torque between them will have passed through a set of positive and then negative values.

If the 19th harmonic wave is examined it will be found to have the same properties so that it also produces torque depending on rotor position and goes through a complete cycle as the rotor is moved one rotor tooth pitch. This was one of the requirements of a theory that would agree with the known facts.

We have yet to investigate the effect of other pairs of harmonic fields and it is now proposed to examine the 5th harmonic. The rotor 5th harmonic wave has been shown to be a result of current induced in the rotor bars by the 23d stator harmonic. The relation between the rotor 23d and rotor 5th is shown in figure 5*a*. For the stator it is necessary to select a particular coil throw from which the relation of 23d and 5th can be worked out as shown in appendix *B*. This has been done and is shown in figure 5*b*. Now if the same assumption is made as before and we place the stator and rotor 23d harmonic fields 180 degrees apart, the two 5th harmonic waves fall in the positions shown in figure 5*c*.

The next step is to move the rotor to a new position and see what happens to the two 5th harmonic waves. If we select one-fourth of a rotor slot pitch for the first point as before we reason as follows. The 23d rotor field must bear the same relation to the 23d stator field in all positions of the rotor since it is induced by it. The rotor must therefore be pictured as it would be after the lapse of sufficient time for the 23d harmonic to move one-fourth of a rotor bar pitch which is 5 fundamental electrical degrees or 115 degrees based on the 23d harmonic wave length. But during this period the rotor 5th harmonic would have moved 115 degrees of its own wave length since all waves move equal parts of their wave lengths in a given time. Converting both distances to degrees of the 5th harmonic wave and noting that both waves move in a negative direction the relative movement of the 5th with respect to the 23d and hence with respect to the stator 5th is,

$$115-115\times 5/23=90 \text{ degrees} \tag{4}$$

Here again we find that the 5th harmonic waves behave in the same manner as the 17th and 19th in that displacement of the rotor causes them to move apart and thus produce torque and the torque cycle requires a displacement of one full rotor bar pitch for its completion. In fact all harmonic pairs that exist follow this same rule.

This establishes a series of torque cycles, each arising from a particular harmonic pair and all existing simultaneously and having the same dependence on rotor position over a slot pitch. Two questions then remain to be answered. First, what are the magnitudes of the various torques? Second, what about the phase relations between the several torque cycles?

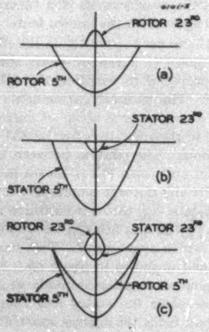

Figure 5

(*a*)—Relation of rotor 5th and rotor 23d

(*b*)—Relation of stator 5th and stator 23d for a particular winding

(*c*)—Relation of stator and rotor 5th-harmonic waves when the rotor 23d is induced by the stator 23d

Note: Waves are not drawn to scale

In answer to the first question, table II has been prepared from calculations on a particular motor by using the torque formula developed in appendix *C*.

The second question, that of phase relation of the torque cycles, is important and is responsible for some of the anomalous results that have been observed. It will be considered in detail in the following section.

6. Relation Between the Various Torque Components

It is evident that there are two possible relations between the rotor and stator waves of a given harmonic when the rotor is in the position shown in figure 4*a*. The two waves are either in phase or 180 degrees out of phase. If they are in phase any movement of the rotor shifts their relative positions in such a way that the resulting torque tends to return the rotor to its original position. This, then, is a stable zero position. On the other hand if the rotor and stator fields are in direct opposition, movement of the rotor shifts the rotor field so as to produce torque assisting the rotor movement. In this case the original position is an unstable zero point.

Since all torque cycles repeat in the same space angle, they either add or subtract and all that remains to be done is to note whether the rotor and stator waves are in phase or out of phase for each harmonic in the original position. As noted above certain harmonics will be found to be one way and others the opposite way for any given winding. Table II has been arranged to show these relations for a specific case. The important fact brought out by this table is the way in which the coil span affects the final results. Thus for a given number of rotor and stator slots and phases there is a wide variation in the locking torque depending on the coil span used. This variation is partly due to the change in magnitude of certain harmonics but the more important cause is the cancellation of forces as a consequence of their phase positions.

Test Results

In order to confirm the theory developed here a two-pole motor having 24 stator slots and 18 rotor slots was wound successively with four sets of coils, each having a different coil span. The number of turns and the operating voltage were adjusted so that the fundamental flux density was the same in all cases. A test of the locked torque variation was made for each winding with two different rotors.

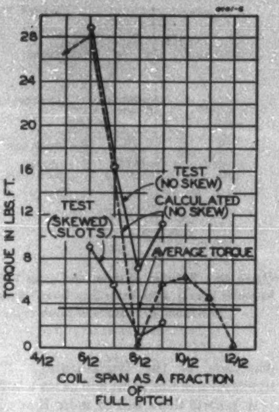

Figure 6. Amplitude of locked-rotor torque variation as affected by coil span. (The total spread between maximum and minimum torque is twice the amplitude shown here)

Curves apply to three-phase motors with 24 stator and 18 rotor slots per pair of poles

One rotor had no skew while the other was skewed a full rotor-slot pitch. The readings were taken at half rated voltage to avoid abnormal heating and consequent changes of resistance.

A sample set of test readings is plotted in figure 1 showing the torque variation as the rotor is moved through a rotor-slot pitch. A minor variation in current occurs also and a curve showing this is included. In figure 6 the amplitude of the torque variation for each of the tests has been replotted to show the effect of a change of coil span. A line showing the average value of the locked torque is included to emphasize the enormous variation that occurs with certain coil spans.

The calculated curve which is shown was worked out in accordance with appendix *C* and applies to the case of the straight-slot rotor. The agreement between test and calculated values, while not as close at all points as might be possible had more rigorous methods been used, seems to indicate that the analysis is essentially correct.

A number of such calculated curves have been worked out for other slot ratios and checked against available data from test files. In most cases fairly satisfactory agreement has been found. The effect of skew has not been calculated in detail but approximate methods of taking it into account can be devised.

In the interest of accuracy it should be recorded that some of the tests, particularly those with no skew, showed an additional variation having a cycle of one-fourth of a rotor-slot pitch. No attempt has been made to account for this component of the torque variation but it is probable that accurate plots of the air gap flux would reveal the cause. Figure 8 shows this type of variation.

The calculated curve of figure 6 is applicable to any motor having the same number of slots per pair of poles as those used for this example provided the torque scale is adjusted to suit the particular values of current as set forth in appendix *C*. For all other three-phase slot combinations which have been investigated so far the general shape of the curve is similar, having minimum points at full pitch and two-thirds pitch.

It may be argued that once the causes of dead points are understood there should be little need to calculate their effects accurately since most designers will simply avoid slot numbers that produce them. The fact remains that other considerations may sometimes determine the slot numbers and thus a means of finding the best coil span is useful.

Rules to Avoid Dead Points

Since there must be stator and rotor harmonics of the same order traveling in the same direction to produce dead points, trouble can be avoided in the case of integral-slot windings by choosing a number of rotor slots which is not a multiple of the number of stator phase belts. For fractional-slot windings of the balanced type the rule is as follows: Avoid a number of rotor slots which is a multiple of the number of phase belts divided by *Y*, where *Y* is the denominator of the fraction, reduced to its lowest terms, expressing the number of stator slots per pole per phase.

If, for any reason, it is desirable to use one of these vulnerable slot ratios a coil span should be used that will minimize the dead-point effect.

A skewed rotor will always decrease the dead-point effect.

Previous Work

After the present study had been completed it was found that the idea of positive and negative signs for the torque components was not original but had been developed independently by Dreyfus[1] in Sweden. It was used later by Richter[2] in Germany and included in his "Elektrische Maschinen." Unfortunately there appears to be no English translation of either Dreyfus' paper or Richter's books and so their results have not had the appreciation in this country that they deserve.

A German investigator, Möller,[3] has taken a series of tests with various slot combinations. His tests showed strong locking with most of the combinations having a slot difference which is a multiple of the phase belts but he also got a weak locking torque in cases where the difference was a multiple of half the phase belts. The latter he attributes to a possible second harmonic of the slot pulsation. The coil span of the stator coils is not stated and no indication is given that its effect was considered important.

Gray[4] discusses the question of dead points and attributes the cause to permeance variations entirely. He shows a test on one motor in which most of the torque variation has a space distribution corresponding to a fifth harmonic of the rotor slot pitch. His motor has five stator slots for each four rotor slots but the numbers of poles, phases, and total slots are not given.

A discussion by Cotton[5] points to permeance variations as the principal cause and states that a common factor for slot numbers is to be avoided. Say and Pink[6] state that locking at standstill occurs when the stator and rotor slots are the same in number or if one is a multiple of the other.

The most recent reference to the subject before the AIEE occurred during the discussion of E.E. Dreese's[7] 1930 paper on synchronous running torques.

Appendix A. Magnitude of the Harmonic Fields

1. Stator

The magnitude of the stator harmonic fields which arise from the distribution of the winding can be calculated with fair accuracy by assuming that the slot current is concentrated at the center line of each slot and that the permeance is uniform. With these assumptions,

$$B_{Sn} = \frac{k_n}{nk_1} \tag{5}$$

where

B_{Sn} = maximum value of *n*th harmonic field in terms of the fundamental field.

k_1 and k_n = product of pitch and distribution factors for fundamental and *n*th harmonic.

2. Rotor Fields

The magnitudes of the *m*th harmonics, or incidental fields of the rotor bear a fixed relation to the *n*th harmonic fields. The well-known relationship between the harmonic components of a rectangular wave is that the magnitude of each component is proportional to the reciprocal of its harmonic order. For two fields of orders *n* and *m* resulting from one set of currents the relation between them is,

$$B_{Rm} = \frac{nB_{Rn}}{m} \tag{6}$$

where B_{Rm} and B_{Rn} are the magnitudes of the rotor *m*th and *n*th fields respectively. The problem then is first to find the value of B_{Rn}. One simple, approximate solution that suggests itself is to assume the rotor

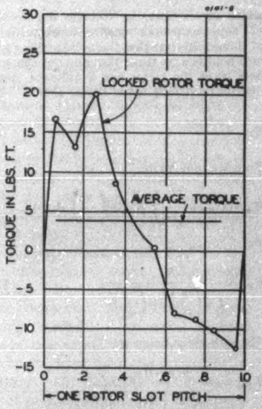

Figure 8. Typical test curve showing variation of locked-rotor torque with rotor position for motor without skewed slots

Motor had 24 stator slots, 18 rotor slots, 2 poles, 3 phases, 7/12 coil span ampere turns equal the stator ampere turns. For the fundamental field or for some of the lower order harmonics this might be done without serious error, but when applied to cases where n is high and m is low it is soon apparent that this simple relationship is far from the truth. The reason for this is that the incidental mth harmonic fields produce flux linkages with the rotor bars which, in the case of a high ratio of n to m, become the determining factors in limiting the rotor current. A more nearly accurate method of finding the value of the rotor fields, though still an approximation, is to equate the rotor bar voltage set up by the stator nth field to the sum of the voltages due to the rotor nth and mth fields.

Thus,

$$E_{Sn}=E_{Rn}+E_{Rm1}+E_{Rm2}+\ldots \tag{7}$$

where,

E_{Sn} = rotor bar voltage induced by stator nth harmonic.

E_{Rn} = rotor bar voltage induced by rotor nth harmonic.

E_{Rm1} = rotor bar voltage induced by rotor m_1th harmonic.

E_{Rm2} = rotor bar voltage induced by rotor m_2th harmonic.

If we use B with its proper subscript to represent the maximum flux density of the various fields then, using per-unit notation,

$$E_{Sn}=B_{Sn} \tag{8}$$

$$E_{Rn}=B_{Rn} \tag{9}$$

$$E_{Rm1}=\frac{nB_{Rm1}}{m} \tag{10}$$

$$E_{Rm2}=\frac{nB_{Rm2}}{m} \tag{11}$$

which states that the voltages due to the nth fields are proportional to the magnitudes of those fields but that the voltage due to an mth field is n/m times the value of the mth field since the latter has a different space distribution. We noted before that:

$$B_{Rm}=\frac{nB_{Rn}}{m} \tag{6}$$

Thus we may write,

$$B_{Sn}=B_{Rn}+\left(\frac{n}{m_1}\right)^2B_{Rn}+\left(\frac{n}{m_2}\right)^2B_{Rn}+\ldots \tag{12}$$

and,

$$B_{Rn}=\frac{B_{Sn}}{1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2} \tag{13}$$

The mth rotor fields are:

$$B_{Rm1}=\frac{n/m_1\ B_{Sn}}{1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2} \tag{14}$$

and,

$$B_{Rm2}=\frac{n/m_2B_{Sn}}{1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2} \tag{15}$$

Expressed in terms of the fundamental stator field density, and the pitch and distribution factors, the rotor mth fields are,

$$B_{Rm1}=\frac{Kn}{m_1\ {}_1\left[1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2\right]} \tag{16}$$

$$B_{Rm2}=\frac{Kn}{m_2k_1\left[1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2\right]} \tag{17}$$

Appendix B. Phase Relation Between the Harmonic Fields

If the fundamental fields due to each of the coils of a phase belt are added together the vector relations are shown in figure 7a. The vector representing the resultant field for the group lies at the center of the group of individual vectors.

A similar vector addition for the fifth harmonic fields of the phase group is shown in figure 7b. The angle between vectors is now five times the angle between fundamental vectors. Here again the resultant is located midway between the second and third vectors.

Figure 7c shows the addition of vectors for the seventh harmonic fields but this time the resultant vector is negative and therefore lies 180 degrees from the dotted line representing the center of the group.

Continuing with the other harmonic fields it is found that some have a positive resultant located along the center of the group while with others the resultant is negative. Thus with respect to the resultant fundamental field certain of the harmonic fields maintain the same phase relation that existed for a single coil while for others the effect of grouping a number of coils together in a phase belt is to reverse the phase relation of fundamental and harmonic. The term phase relation is used here to indicate whether at the point of positive maximum of the fundamental the given harmonic has a positive or a negative value. To find whether a given harmonic will reverse its position for a group of coils as compared to a single full-pitch coil it is only necessary to solve the expression for the sum of a group of vectors separated by a uniform angle and note the algebraic sign. If Σ is the resultant vector,

$$\Sigma=\frac{\sin Nn\frac{\alpha}{2}}{\sin n\frac{\alpha}{2}} \tag{18}$$

where N is the number of vectors and $n\alpha$ is the angle between them. When Σ is positive the harmonic under consideration keeps the same relation to the fundamental that it has when a single coil is examined. If the sign is negative the harmonic reverses.

By a similar process the effect of chording the winding may be investigated. In this case the top and bottom layers of the winding are considered as two groups of coils displaced in phase by the angle by which the coil span differs from full pitch. The expression for Σ is solved for the case of two vectors differing by n times this angle and the algebraic signs determine whether or not the nth harmonic is reversed due to chording.

These relationships can be kept clear by using positive and negative signs for the distribution or breadth factor and for the chord or pitch factor. Thus the factor Kn in appendix A which is the product of these two factors will be either positive or negative. The torque formula in appendix C will also give either positive or negative results depending upon the algebraic signs of Kn and Km. Table II shows the torque components with their algebraic signs for a typical motor with various coil spans.

Appendix C. The Torque Formula

The torque developed between stator and rotor fields of the same harmonic order varies with the phase relation between them, reaching a maximum at 90 degrees. The maximum torque is proportional to the product of the magnitudes of the two fields. When dealing with several harmonics it must be kept in mind that for the same maximum flux densities the torques of various pairs of fields are also proportional to the harmonic orders. From these elementary considerations we may write:

$$\text{Torque}\propto m\times B_{Rm}\times B_{Sm} \tag{19}$$

for any one particular harmonic. Substituting the expressions for stator and rotor fields and including a proportionality factor the torque in per unit terms is,

$$\text{Torque}=\frac{K_nK_m\ I_L^2}{mK_1^2\left[1+\left(\frac{n}{m_1}\right)^2+\left(\frac{n}{m_2}\right)^2\right]I_1I_m\sin\theta} \tag{20}$$

where,

I_L = locked current

I_1 = rated current

I_m = magnetizing current

θ = phase angle between I_1 and I_m

A Decade of Progress in the Use of Electronic Tubes

Part I—In the Field of Communication*

S. B. INGRAM
MEMBER AIEE

THE dependency of the art of communication on the science of electronics is so great as to make a review of progress in electronics almost of necessity a review of the field of communications itself. While it is true that the early forms of telephone and radio communication advanced to a degree without the use of electronic devices as we know them today, the recognition of the vacuum tube as an amplifier and generator of high-frequency alternating currents in the years just preceding the first World War marked a turning point in the development of the communication art. From that day to this the progress of electronics and communications has gone hand in hand. The need of the communications engineer for new electronic tools has kept him continually urging the electronics engineer to improve old devices and to originate new ones, and each time the efforts of the latter have been rewarded with success, the fruits of his work have been immediately applied to produce new and more startling miracles of long-distance communication.

Because of the close relationship of electronics and communications it is necessary in reviewing the progress of the last decade to keep in mind that it is progress in electronics and not in communications which is our theme. It will be necessary to survey the trends in communications during the period under review, but then it will be necessary to ask to what extent the progress which has been made is due to advances in the electronic field and what advances in the electronic devices themselves have laid the foundation of this progress. There has been no attempt made to make this review comprehensive in the sense that it include all items of progress which are of individual interest. To do so would make it merely a catalog of these many advances and an index to the periodical literature of the subject. Rather the object has been to trace the most significant trends of development in the various fields and to emphasize those lines of advance which appear to be most closely related to the general direction of progress in the several fields of electrical communication.

The Trend in Radio—to Ultrashort Waves

The history of radio has seen a continual demand for expansion of the usable region of the frequency spectrum. Because the number of available communication channels is limited it has been necessary to ration the frequency spectrum by governmental regulation and international agreement among the various users and classes of service. Existing services, most of which are experiencing a continual expansion, have completely absorbed the allocations in the intermediate and short-wave band and leave nowhere to place new services but in the ultrashort-wave region above 30 megacycles. Not only are the new services forced to the ultrahigh frequencies by congestion at the longer waves, but in some cases they are themselves of such a nature that an adequate number of channels with the necessary band width can be obtained only at the high frequencies. Television and wide-band frequency modulation are cases in point. A band width of over four megacycles is required to transmit a modern high definition television image. Frequency-modulation systems at present proposed require a 150-kilocycle band. Radio relay systems for these same services will require band widths at least as great and can obviously be accommodated only in the ultrashort-wave region. The development of these and other wide-band services is therefore dependent on satisfactory means for working at ultrahigh frequencies.

Another reason for the current interest in ultrashort waves is that new services are developing making use of their unique transmission properties. Their very shortness makes practical the construction of directive antenna systems and this can be more easily accomplished the shorter the waves. Directivity, which of course can be applied only in the case of point-to-point services, greatly reduces the power requirements on the transmitter. For broadcast services the problem of interference between stations is simplified because the transmission of ultrashort waves is approximately limited to line-of-sight paths. To relate their propagation exactly to line of sight as has been frequently done in recent years is an oversimplification of the problem but it is probably true that the ultrashort waves will find few applications for ranges beyond 100 miles and that interference need not be feared beyond a few hundred miles at most.

In the very front of this field, in the range of centimeter waves, that is above 300 megacycles, the directive possibilities of ultrashort-wave systems become particularly marked. Commercial applications in this region are as yet few, but may be expected to increase rapidly in the future. As examples of the unique type of problem capable of solution only by the use of centimeter-wave technique may be cited the development of the absolute altimeter to measure the height of an airplane over the terrain by the reflection of radio waves[6] and a 40-centimeter airplane blind-landing system.[7]

The Trend in Television—to Electronic Television

Television is an art which has developed almost entirely within the last 15 years. In no field is the close relationship between communications and electronics better illustrated than here. All modern systems of television depend on the modulation of a carrier frequency wave by a video signal. This video signal is derived by scanning the picture in a series of horizontal lines, the amplitude of the video signal varying with the brightness of the individual picture element traversed by the scanning beam. The transmission of the modulated carrier is a radio problem in which the principal difficulties to be overcome are those related to the wide band required for a high-definition picture and to the high frequencies assigned for television transmission. At the receiver, demodulation and a second scanning process synchronized with the first are required to reconstruct the picture. The earlier systems of television used mechanical scanning methods at both transmitter and receiver. These mechanical scanning methods had numerous disadvantages. They called for rapidly rotating mechanical elements, perforated disks, lens disks, drums bearing mirrors, and numerous other devices of a mechano-optical nature. It is inherently more difficult to synchronize two rapidly rotating mechanical systems than two electrical circuits on account of the inertia of the mechanical parts. It was hard to get sufficient optical efficiency either for satisfactory studio technique at the transmitter or a sufficiently bright image at the receiver. All these difficulties were magnified when the progress of the art called for the production of a high-definition picture, the mechanical problems because a higher scanning speed was required, the optical difficulties because the light available was proportional to the area of the scanning spot and high definition meant a smaller spot. A solution was sought in electronic television. It was found first at the receiver, for the cathode-ray tube which had been used for some time as a laboratory tool had all the elements of an electronic scanning device for a television receiver and needed only to be adapted and improved for the purpose. For the transmitter, however, completely new devices had to be invented and they came in the form of the Iconoscope, the image dissector, and later modifications of these. Today electronic methods of scanning have replaced mechanical methods practically universally at the transmitter although it is as yet too early to say that some place may not be retained for mechanical systems, for example in the scanning of film. At the receiver electronic methods are also most generally used, the Scophony system[61] being the outstanding example of a mechanical scanning method still successfully holding a place for itself.

The Trend in Telephony—to Broad-Band Carrier Systems

Electronic devices have played a major part in the field of long-distance telephone transmission for many years. In local circuits the attenuation is small enough so that no amplification between the transmitter and receiver is necessary to counteract it, but in all long-distance circuits attenuations are so great that without the vacuum-tube amplifier, or telephone repeater as it is called, communication would be impossible. The earlier systems were voice-frequency systems in which one pair of conductors was used to carry each conversation. The advantages of carrier systems in which one pair of conductors could carry several frequency channels each modulated with its own voice current were early recognized. Such systems generally carrying three speech channels have been in use for 20 years or more. The total frequency band transmitted in these earlier systems was however limited to about 24 kilocycles. Within the last decade tremendous impetus has been given to the development of broad-band carrier systems where the frequency band transmitted may be as high as several thousand kilocycles.

There are two general types of broad band carrier systems.[8–10] There are those in which, by the addition of repeaters and terminal equipment, the carrying capacity of existing conductors both cable and open wire can be greatly increased.[11–14] These systems in general will accommodate from 12 to 16 channels per pair and utilize carrier frequencies up to 145 kilocycles. They are extremely important from an economic standpoint since they permit great economy in the amount of plant required to accommodate an increase in traffic when existing facilities are fully utilized. Then there are the very broad-band coaxial-conductor systems.[15,16] The circuit in this case consists of two concentric conductors separated by small dielectric spacers. Such systems are capable of transmitting exceedingly high frequencies with a maximum degree of shielding from outside interference. Their importance lies not only in their ability to transmit as many as several hundred telephone conversations simultaneously, but also in the fact that they present the only practical means at present in prospect for setting up wire transmission systems capable of transmitting high definition images in television broadcasting networks.[17] The detailed discussion of broad-band carrier systems is outside the scope of this paper. What does concern us here is the problem of amplification which must be accomplished by electronic means. In the cable carrier system attenuations run as high as 4 decibels per mile, in the coaxial system 8 decibels at two megacycles. If we envision 1,000 miles of coaxial circuit the attenuation which has to be compensated by amplification amounts to 8,000 decibels. This represents a total power amplification between terminals of 10^{800}. The requirements on the amplifiers of such a system are obviously very stringent. They must have a high degree of stability so that the power level at the terminals shall be constant, they must be linear so that the intermodulation products which would produce interference with one voice channel by another shall be negligible, and they must be capable of transmitting a wide band of frequencies. Such requirements can be met only by the stabilized-feed-back amplifier[74] which is an electronic circuit development of the highest order of importance. Without this solution of the amplifier problem broad-band carrier systems as we know them today would be impractical.

While considering carrier telephone systems we should pause to note one of the losses of electronics as a contender for supremacy in the telephone transmission field. Copper-oxide modulators and demodulators have in general proved superior from the standpoint of compactness, economy, and ease of maintenance to the vacuum-tube circuits formerly used for this purpose.[18]

Progress in Electronic Devices

So far consideration has been given to the trend of progress in the several major divisions of the communications field and it has been shown how electronics has played an important role in contributing to this progress. The remainder of the paper will be devoted to a review of progress more specifically in the electronic devices themselves. In considering these it will be convenient to divide the devices into several broad classes: those depending primarily on thermionic emission for their operation, those depending on secondary and photoelectric emission and the new science of electron optics, and those based on the phenomena of gas discharges. Finally a few of the most fundamental electronic circuit developments will be described.

Thermionic Devices

The extension of radio into the ultrahigh-frequency portion of the spectrum has been paralleled by a corresponding growth of interest in the development of vacuum-tube devices for use at these frequencies. Those which have found most general use up to the present time are modifications of the familiar three-element or negative-grid vacuum tube designed particularly to fill the requirements of ultrahigh-frequency operation.[19-21] Major development efforts have proceeded in two directions; toward the generation of relatively small amounts of radio-frequency power at higher and higher frequencies, attempting to extend the useful portion of the radio spectrum into the region of the centimeter waves, and toward an increase in the usable range of power at more moderate frequencies in the lower parts of the ultrashort-wave region where television and frequency modulation have brought a commercial demand for radio transmitters. In the former class the frequency limit has been pushed up to 1,800 megacycles; in the latter water-cooled power amplifiers capable of power outputs of approximately 10 kw at 100 megacycles are now commercially available.

The tendency of negative-grid tubes to produce unwanted oscillations due to the feedback of power from the output to the input circuits makes the problem of producing amplifiers at the ultrahigh frequencies more difficult than that of producing satisfactory oscillators. Methods of neutralization which can be used at lower frequencies to prevent these oscillations from occurring become inadequate at the higher frequencies because of the inherent difficulties of circuit technique. The problem has been solved by the construction of special push-pull pentodes containing two tube structures within one envelope.[22,23] With such tubes, stable amplifiers with power outputs of 10 watts at 250 megacycles and some measurable amplification as high as 500 megacycles have been constructed.

Negative-grid tubes are used both as oscillators and amplifiers. Two other devices, both by their nature incapable of amplification but interesting as oscillators because their power-generating capacity exceeds that of negative-grid tubes in the centimeter-wave region, have received considerable attention.[24-26] These are the positive-grid or Barkhausen oscillator and the magnetron. Of these the latter has received the greater attention. Magnetrons depend for their operation on the curvature of the path of the electrons as they move under the influence of the electrostatic field between a filament and a surrounding cylindrical anode placed in a homogeneous magnetic field along the axis. Two general modes of oscillation exist. In the first the static negative-resistance characteristic of the tube is utilized. Operating in this mode magnetrons have been used to produce power outputs of as high as 450 watts at 46 centimeters.[27,28] Efficiencies in the range from 30 to 60 per cent have been reported. While this is considerably better than has been obtained with the negative-grid triode, there are difficulties of frequency stability and modulation with magnetrons, and these together with the additional complication of the equipment required to supply the magnetic field make them rather poor competitors of negative-grid tubes at these frequencies. The second type of magnetron oscillation is one in which the transit time of the electrons is approximately equal to the period of the radio-frequency output.[29] Operating in this manner the magnetron has established the record for ultrahigh-frequency wave generation at 61,000 megacycles corresponding to a wave length of only 4.9 millimeters.[30]

For the conventional negative-grid triode the maximum power-handling capacity has been shown to vary inversely as the square of the maximum frequency at which the tube is designed to operate[19] so that some new principle must be called into play if significantly greater power outputs are to be realized in the centimeter-wave region. Very recently tubes operating on such fundamentally new principles have occupied a great deal of attention by research workers and show promise of giving performance considerably better than that yielded by negative-grid tubes both with respect to power output in the centimeter-wave region and to their maximum frequency of operation. They differ in their principles from conventional tubes in that the radio-frequency output is taken from the electron stream by induction in an anode element which is not the same as that which collects the current and which therefore does not need to dissipate the d-c power. The variations in electron density capable of inducing these radio-frequency currents are produced in two different ways. In the inductive output tube[31] the conduction current is modulated by a cathode grid structure exactly as in the ordinary triode. In the "velocity modulation" tube[32] or in the so-called "klystron"[33] the principle of velocity variation is used. A stream of electrons accelerated from a cathode passes through two grids between which a radio-frequency signal is applied. This signal retards or accelerates the electrons according to the phase of the cycle at which they happen to pass the grid giving rise to velocity variation of the beam which then passes through a field-free "drift space" in which the faster electrons catch up to the slower ones. A bunching or conduction current variation of the beam is thus produced and renders it capable of generating radio-frequency currents in the output electrodes by induction. Tubes of this design overcome two limitations inherent in the negative-grid type. Higher efficiencies may be attained because the output electrode is not called upon to dissipate the tube losses and in the case of velocity-variation tubes transit time through the radio-frequency input section of the device is much less than in triodes since the electrons are moving with high velocity when they enter this space instead of having to accelerate from zero velocity. This greatly reduces "active grid loss", that is, the increase of grid driving power required as the operating frequency is increased which is directly due to the transit time becoming comparable in magnitude with the radio-frequency period and which is the fundamental limiting factor in the high-frequency operation of negative grid tubes. In contrast to the magnetron, velocity-variation tubes are well suited to operation as radio-frequency amplifiers. Experimental data on performance reported in the literature are meager as yet but operation at frequencies as high as 6,000 megacycles (five centimeters) and oscillator power outputs of 500 watts at 750 megacycles have been reported.[1]

Space will not permit the mention of many detailed improvements in the general field of thermionic vacuum tubes, but some reference should be made to the application of electron optics to thermionic devices in the beam power tube.[38] In this tube the electron stream, which is confined to move in beams by accurately lined up grids and by electrostatic deflecting plates, produces a space-charge potential minimum in the neighborhood of the plate which suppresses secondary emission just as the retarding field of the suppressor grid does in the ordinary pentode. Such tubes have received wide acceptance as power amplifiers on account of the high efficiency obtainable with them.

Wide-band amplifiers of the type required in television receivers and in broad-band carrier systems require tubes with a high ratio of transconductance to interelectrode capacitance. Recently developed tubes for these systems have shown considerable advances in this respect[39,40] and in view of the increasing importance of broad band systems, further advances can be anticipated along this line.

Devices Based on Secondary Emission, Photoelectric Emission, and Electron Optics

The devices which we will consider in this section are largely a group whose development has been brought about by the needs of the new art of electronic television. They have been made possible by the great advances made in the underlying science of electron optics, and by putting to work the phenomenon of secondary emission. The knowledge and application of the laws of electron optics have progressed to the point where beams of electrons can be focused and directed in accord with well-defined and well-understood laws. Electron images can be projected in space by electron lenses which consist of electric fields set up by suitably disposed electrodes at the proper electrical potentials or by magnetic fields from the appropriate current-carrying coils.

The basic phenomena of secondary emission have been known for many years. Their effect in modifying the characteristics of vacuum tubes was also well known, the third grid in the ordinary pentode being introduced specifically for the purpose of suppressing secondary electron emission from the plate. It was not however until recently that it was demonstrated that since one electron impinging on a suitable surface with appropriate energy has the ability to release more than one secondary electron, it is possible to build electronic amplifying devices based on the phenomenon of secondary emission. These devices are called secondary emission multipliers.[41,42,57] In general they consist of a number of successive electrodes whose surfaces have been suitably treated to give them a high secondary emission ratio and which are maintained at sufficient potential difference to give an optimum over-all multiplication to the device. If under these conditions a secondary emission ratio of m prevails, the multiplication in k stages is m^k. Values of secondary emission ratio in present-day multipliers are typically in the neighborhood of four and the number of stages varies up to 16. Total over-all amplifications of several billion have been reported.[43] The limiting output is determined by power dissipation in the last stage and defocusing of the electron beam due to space charge. Multipliers can be associated with various types of input. When applied to a tube with a photoelectric input, multipliers can readily be produced with sensitivities as great as 30 milliamperes per lumen or greater.[44]

One advantage of such multipliers over the combination of a photoelectric cell and a thermionic amplifier is that no coupling resistor is required between the photoelectric-cell output and the first stage of amplification. Thermal noise in this resistor is therefore eliminated, and for this reason the photoelectric multiplier is capable of operating at much lower levels of illumination than the photoelectric cell with thermionic amplification.[41,45] As described below, multipliers can be associated directly with the output of television pickup devices. Finally, secondary-emission multiplication applied to the output of an ordinary thermionic vacuum tube offers attractive possibilities in the field of wide-band amplification since circuit problems could be greatly simplified if an amplifying device were available capable of giving a greatly increased gain per stage. The multiplier can do this and has the further important property that its amplification is essentially independent of frequency up to many megacycles where transit time becomes a limiting factor. One interesting commercial tube in which one stage of secondary electron multiplication is added to an ordinary tetrode, has a transconductance of 14,000 micromhos.[46]

The electron optical problems of multiplier design are worthy of special attention because of the ingenious methods which have been devised for their solution. Earlier multipliers used magnetic focusing to assure that all the electrons originating on one stage were suitably collected on the succeeding one. Present-day multipliers are generally of the electrostatic type, the electrodes being so shaped that the equivalent focusing action is obtained. The problem of determining electron trajectories in ordinary multiplier structures is too complex to admit of ready mathematical solution. Electrolytic tank models for determining electric fields in complicated structures and mechanical models for determining electron trajectories have proved invaluable design tools.[43,44] In the latter method metal spheres rolling on a stretched rubber membrane whose slope simulates the electric fields of the tube elements can be shown to trace out the trajectories with a highly practical degree of accuracy.

In electronic television systems four types of pickup tubes are today in common use. The first is the image dissector.[55–8] In this tube the visual image is focused on a photoelectric surface. The photoelectrons emitted are focused by means of an axial magnetic field in the plane of the scanning aperture. This whole image is then moved back and forth across this stationary scanning aperture, the image thus being "dissected." Since the aperture must be minute for a high-definition television picture, the current is very small and passes immediately into an electrostatic electron multiplier for amplification. The output from the last stage of this multiplier is the video signal.

The second pickup tube is the Iconoscope.[55,59–64] The essential element of this tube is the mosaic plate consisting of minute islands of photoemissive substance backed by a thin insulating layer of mica the reverse side of which is covered with a conducting coating. This layer forms the output electrode of the device and to it the elements of the mosaic are capacitively coupled. The optical image is focused on the mosaic. Photoelectrons are emitted from the elements causing them to assume a potential which is dependent on the intensity of the light falling upon them. The mosaic is scanned by an electron beam from an electron gun. This electron beam impinging on the surface under conditions in which the secondary emission ratio is greater than one recharges the element to a definite equilibrium potential and the variations in the recharging current required constitute the video signal which is transmitted to the output circuit through the capacity of the mosaic.

The Iconoscope has the important advantage over the image dissector that its elements act to store charge during at least a portion of the scanning time and this stored charge is then swept away quickly during the traverse of the scanning beam. This gives it a considerably greater sensitivity than the image dissector and makes it suitable for taking scenes under many conditions of illumination where the image dissector is inadequate. Balanced against this is the presence in the Iconoscope output of a spurious signal or "dark spot" arising from the redistribution of photoelectrons and of secondary electrons from the scanning spot over the whole mosaic surface. This spurious signal must be balanced out by the electrical insertion of a compensating signal from a special electrical network. The image dissector also has an advantage in being a directly coupled device the output of which contains information as to the general level of illumination of the picture. The Iconoscope being capacitively coupled gives information only as to variations in illumination, and its output must therefore be continuously monitored to adjust for changes in background illumination as well as for the dark-spot signal just mentioned. At present the Iconoscope type of camera appears to have most general applicability on account of its greater sensitivity but the simplicity of operation of the image dissector gives it a field of use in special cases, for example in pickup from motion-picture film where adequate levels of illumination are easily obtained.

Sensitive as the Iconoscope is on account of its charge-storing property, still more sensitive pickup devices are urgently required by television techniques. Tests show that the charge storage in the mosaic is not greater than five or ten per cent what would be expected under ideal charge-storage conditions, being low because the field which attracts the photoelectrons from the mosaic is small and because only a fraction of the secondary emission current reaches the anode. The super-emitron[64] or its American counterpart the image Iconoscope[65] increase this low efficiency. In these tubes the photoelectric surface is separated from the mosaic, an electron image of the electrons emanating from the former being focused on the latter by means of an electron lens. This mosaic is then scanned as in the Iconoscope. This arrangement enables two gains to be made. A more efficient photoemissive surface can be produced and the photoelectrons may be drawn away from it under conditions of voltage saturation. An over-all gain in sensitivity of about ten times over the Iconoscope has been achieved in practical tubes of this type. They are used to some extent in commercial television pickups particularly under low outdoor conditions of illumination.

Another interesting pickup tube, the "orthicon," has recently been described.[66] It differs from the Iconoscope in that the mosaic is scanned by a beam of low velocity electrons. The photoelectrons leave the surface under voltage saturation conditions giving the tube an over-all high efficiency and making the light response linear. Since the energy of the scanning electrons is low, secondary emission plays little or no part in the operation of the device and the level of the spurious signal is low. Such devices appear to offer promise but problems of focusing a low-velocity beam are formidable and the definition of pictures produced with such tubes do not at present compare favorably with those obtained with the Iconoscope.

For the picture tube in television receivers the conventional cathode-ray oscilloscope tube needed only to be adapted, although many detailed improvements have been required. Electron guns for producing high-current electron beams of accurate focus have been developed.[68] Great progress has been made in the production and use of fluorescent materials.[69] Much of the current development effort is directed at the production of tubes with a sufficiently bright image to enable optical projection onto a large screen.[70] Tubes for this purpose with electron-beam energies as high as 80 kv are under laboratory investigation.[49]

Gas-Discharge Devices

In communication systems gas-filled tubes have found most general use as rectifiers to provide d-c power from a-c supplies or as relay devices in control and signaling systems. Use in circuits carrying the communication signals themselves has proved impractical because of the noise inherent in the gas discharge itself and various proposals for gas-filled amplifying devices have so far proved impractical on this account.

In radiobroadcast transmitters, mercury-vapor rectifiers have largely replaced rotating machines for providing d-c supplies. Mercury-vapor rectifiers have been found to give efficient service with a minimum of maintenance for all outputs up to 20 kv and 100 amperes.

Thyratrons or gas-filled rectifiers which contain a grid to control the starting of the discharge are also becoming widely used in rectifiers for battery charging in telephone central offices. By utilizing grid control in such tubes, regulated rectifiers can be built which automatically adjust the charging rate of the battery in such a way as to hold its terminal voltage constant as load and line voltages vary.[71,72] This condition makes for long battery life and also eliminates the maintenance required by manually adjusted chargers.

In control and signaling systems one type of gas-filled device, the cold-cathode tube,[73] appears to offer prospect of extensive use. In its simplest form it consists of a gas discharge tube containing a cathode, an anode, and an auxiliary electrode. The passage of a small amount of current of the order of one microampere to this auxiliary electrode will control the starting of the anode current which can then be as large as 10 to 100 milliamperes in existing types. The tube thus functions as an extremely sensitive relay. Dissimilarity of cathode and anode can be used to provide a rectification property. In recent years cold-cathode tubes have been extensively applied in four-party selective-ringing circuits for the selective signaling of telephone subscribers on party lines.

Electronic-Circuit Developments

The importance of the stabilized-feed-back amplifier in wide-band carrier telephone systems has been brought out. The principle of such amplifiers is basically very simple.[74] A portion of the output is fed back to the amplifier input usually through an attenuating network in such a manner as exactly to oppose the input signal. This reduces the over-all gain of the amplifier and also reduces noise and distortion usually in the same proportion. With modern high-amplification-constant vacuum tubes the decrease in gain can be readily restored and the net result is an amplifier which is superlatively better than the simple amplifier without feedback. The first major advantage of such amplifiers is the linearity of their characteristics. In carrier systems this is important since intermodulation which causes interference between the various speech channels can be practically eliminated. To obtain this same result without the use of stabilized feedback would require the use of vacuum tubes of much larger power ratings operated over a small portion of their characteristics with a consequently greatly reduced efficiency. The second advantage of the negative-feed-back amplifier is its stability. When the amount of feedback is large it can be shown that the over-all amplification depends only on the characteristics of the feed-back circuit and is practically independent of the amplifying circuit. Since the feed-back circuit contains only fixed circuit elements and no vacuum tubes the over-all amplification becomes independent of variations in tube characteristics and supply voltages. This stability is essential in a carrier system which has many repeaters in tandem if the total amplification between terminals is to remain constant. The third advantage is the ease with which the over-all gain and the gain frequency characteristic of the amplifier can be controlled. These are functions only of the feedback circuit characteristic which can be given any desired shape by the introduction of appropriately designed equalizing networks. In carrier systems the attenuation-frequency characteristic of the line and the variations in attenuation-frequency characteristic with temperature can thus be almost exactly compensated by adjusting the gain-frequency characteristic of the repeaters.

A great amount of technical interest and commercial activity is currently being devoted to a new form of radiobroadcasting known as wide-band frequency modulation.[75,76] It is as yet too early to say what the ultimate development of this system will be, but its most enthusiastic advocates foresee the obsolescence of the present system operating within the broadcast band in the neighborhood of one megacycle and the development of a new ultrahigh-frequency system operating on the principles of frequency modulation. In conventional radio-telephone systems the amplitude of the carrier wave is modulated by the audio frequency. In the proposed system the frequency of the carrier is caused to vary back and forth over a frequency band approximately 150 kilocycles in width, the instantaneous deviation of the frequency from the mean being proportional to the instantaneous amplitude of the modulating audio signal. This system has several interesting features as compared with the existing low-frequency amplitude-modulation broadcasting. Natural atmospheric noise is inherently low in the ultrahigh-frequency region of the radio spectrum. Interference from automobile ignition systems, on the other hand, is more severe than at broadcast frequencies. The characteristics of the proposed frequency-modulation system are such that the radio-frequency interference-to-signal ratio may be higher without noticeable interference with the program than is the case with amplitude modulation. The same characteristics of the system which make this true are effective in reducing interference between stations on the same frequency. It is possible with frequency modulation to transmit programs of high fidelity without unduly high expenditures of power at the transmitter but this is done at the expense of using a wider frequency channel.

The extension of high-frequency practice to the centimeter wave region has called for new circuit techniques. As the frequency is increased the lumped inductances and capacities of the resonant circuits decrease and the distributed constants of the connecting leads play a continually greater part in the circuit performance. In the ultrahigh-frequency region and particularly at wave lengths less than one meter, it becomes convenient to do away with the lumped circuit constants altogether and to use instead the resonant properties of transmission lines of either the parallel wire or coaxial types.[77] Such circuits are readily adjustable, convenient to work with, and the mathematical theory of their properties is well understood. At still higher frequencies even transmission-line circuits become impractical but at this point the resonant properties of conducting cavities can be exploited to advantage. It was demonstrated about four years ago[79] that a cavity whose boundary is a good conductor is capable of sustained electrical oscillations at certain characteristic frequencies determined by its geometry and that such cavities may be used advantageously as circuit elements associated either with sources or sinks of electromagnetic wave power. In some recent electronic devices, for example the velocity-modulation tubes and klystrons mentioned above, this principle has been invoked. The tube elements themselves have in effect been set directly into the walls of such resonant cavities.[78]

Closely related to the phenomena of resonant cavities is the propagation of electromagnetic waves through hollow metal tubes or wave guides.[79–84] For simple geometrical shapes the theory of this form of electromagnetic wave propagation is well established.[80] Propagation can take place only when the wave length is less than some critical value which is of the same order of magnitude as the diameter of the conductor. The method is therefore limited to the ultrahigh frequencies. Attenuations even at these extremely high frequencies can be made comparable with those of ordinary coaxial cable at the lower frequencies so that at the moment wave guides appear to offer considerable promise in future wide-band ultrahigh-frequency communication systems. The end of a wave guide may be flared out into a highly directive electromagnetic horn which may be used either as a radiator or receiver of ultrahigh-frequency waves. The resulting power gains are comparable with or even greater than those of the more conventional directive antenna arrays now in general use.[85–8] The rapid development of the understanding of the transmission properties of ultrashort waves in wave-guide systems has provided a further impetus for the development of electronic devices capable of generating and amplifying these ultrahigh frequencies.

Bibliography

No attempt has been made to make the bibliography comprehensive. The aim has been to include papers of most fundamental importance and, where they are available, those of a review nature which will assist the reader who wishes to go more fully into the developments of any particular field. Preference has been given to the literature printed in the English language since it has been felt that this will be of most use to the average reader. In so doing it has not been intended to slight the much excellent work on electronics and communications which has been carried on abroad.

A Decade of Progress in the Use of Electronic Tubes

Part II—In Other Than the Field of Communication*

W. C. WHITE
MEMBER AIEE

Synopsis: The past ten years include nearly the whole period during which electronic tubes have been used outside the communication field. The types of tubes used in this field may be classified into groups, each having properties that make it valuable in certain phases of industry or in specific applications. The references are grouped according to nature of application and represent a selected group chosen by careful elimination from several thousand.

IN comparison with the communication field, the use of electronic devices in other industry has played an entirely different role. In communication in general and in radio in particular, tubes and tube developments have been basic to most improvements. They have been truly called the "heart" of nearly all radio apparatus. In other industry, however, they have in general had to supplant other methods and to compete in highly developed fields of electrical engineering.

The use of tubes in the noncommunication field has passed through several broad phases. At first they were looked upon with a certain amount of mistrust as being rather fragile playthings entirely unsuited for the severe conditions encountered in the industrial field. Next, as a result of the increased popular interest in science and the optimism of the late 20s, they became "wonder" devices and their wide use in nearly every electrical field was freely predicted.

Within the past few years, a more realistic viewpoint has prevailed and much solid progress has been made. It is realized that there is no magic in an electron tube, and the tube must either accomplish something that cannot be done by any other means or make its own way against competition solely on the basis of what it can do for less cost than existing methods.

Scope of This Review

The last decade includes the greater part of tube activity in this field, but reference is necessarily made occasionally to earlier work to clarify or to complete the picture.

Electrons are now known to play such an active part in so many devices that, in the interest of brevity, certain devices are not included in this review. These omissions are neon lights as well as other gaseous light sources, ultraviolet tubes, X-ray tubes, pumped mercury-arc tanks, iron-wire ballast tubes, mercury and vacuum switches, and uses in phonographs and talking moving pictures. This review is also limited to American references in the interest of brevity.

Due to the activity in this field and the relatively long period covered, only a small fraction of the available references are included. Those included were chosen on the basis of availability, general nature of treatment of subject, and their use of further references.

The emphasis in this review has been placed mostly on tube applications rather than the tubes themselves. This has been done because of the wider interest in applications and because the review must be kept to a reasonable length. The references to tube design have been included only when they were important from the viewpoint of new applications or unless similar tubes were not used in communication.

Arrangement of References

In general the references are classified under headings similar to those employed by the AIEE in indexing its TRANSACTIONS in past years.

Factors Favoring the Use of Tubes in Industry

In competing with rotating equipment, the use of tubes eliminates noise, vibration, and the need of special foundations.

The ability to amplify from very low input levels both in high-vacuum and gas-content tubes makes them unique electrical devices. Their amplification can also be made continuously variable rather than step-by-step.

Tubes provide cycle-by-cycle and fractional-cycle control.

Tubes in combination with such devices as thermocouples, microphones, photoelectric cells, and movable capacitance plates permit electrical response to temperature, sound, light, and motion. Therefore, they extend control operations to variations in sensory response.

Tubes also find ready application where they extend certain factors to extreme limits. Timing to very short intervals, response to extremely small electrical quantities, and control from very small movements are examples of this.

They operate relatively independent of frequency in comparison with most other electrical devices.

Factors Retarding the Use of Tubes in Industry

The relatively high cost of tubes in combination with the fact that they are renewable items has retarded their application.

Their mode of operation and application has not been so commonly understood as other electrical devices.

Considerable engineering knowledge and effort are often required to work out a new application successfully and in some cases the expense of this apparently cannot be justified from the viewpoint of available business.

A General Summary of Types of Tubes

The following comments are based on tube types and applications outside the communication field.

HIGH-VACUUM DIODES

These tubes are inherently rectifiers only and are suitable for use where high frequencies are involved. Their use is also limited in general to currents of about an ampere. They are suitable, however, for voltages up to the hundreds of thousands.

The early applications of this type of tube were for the purpose of obtaining high voltage (25 to 150 kv) for smoke and dust precipitation as well as high-voltage cable testing by power companies. This

Paper 40-112, recommended by the AIEE joint subcommittee on electronics, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 25, 1940; made available for preprinting June 3, 1940.

W. C. WHITE is in the vacuum-tube engineering department of the General Electric Company, Schenectady, N. Y.

* A report prepared for the AIEE joint subcommittee on electronics: H. M. Turner, *chairman;* W. R. Brownlee, J. H. Cox, J. W. Dawson, T. F. Gray, S. B. Ingram, D. C. Prince, Joseph Slepian, Thomas Spooner, W. C. White, and T. A. Worcester. Part I appears on preceding pages.

use has continued and grown to some extent. They also find a wide variety of application, but in limited quantities, in laboratories for high-voltage, low-current, d-c power supplies.

HIGH-VACUUM TUBES WITH CONTROL GRID OR GRIDS

This class of tubes involves one or more control electrodes; their chief functions are as amplifiers and oscillators. They range in ratings from less than a watt to over 100 kw.

There are probably hundreds of thousands of these tubes in daily operation in a bewildering variety of circuits. By far the big majority of them are radio-receiving-tube types used in oscillating and amplifying circuits. In some cases, requirements of power output or a special operating condition has dictated special types. Automatic train control, high-frequency therapeutic oscillators, and low-grid-current amplifier tubes are examples of such special designs. There are many others.

The literature contains hundreds of articles on special applications of this class of tube and thousands of references are made to their use in the literature.

HOT-CATHODE GAS-FILLED DIODES

This class of tube is utilized for rectification of heavier currents at lower frequencies and voltages than the high-vacuum type. Gas-filled tubes have a relatively low and constant voltage drop in comparison with high-vacuum tubes.

There is one field where the great majority of tubes of this type are used and that is for low-voltage battery charging. Most of these are tungsten filament, argon-filled tubes for currents under ten amperes, and for direct voltages under 125.

Another group of rectifier tubes of this class utilizes mercury vapor and is suitable for voltages up to about 20,000. Although the great majority of such tubes are used for d-c power supply of radio transmitters, some are used for high-voltage testing and to supply direct current for high-frequency tube oscillators.

Similar tubes are also employed in rectifiers to supply power at the lower standard voltages—125, 250, 500, and 650—to replace power formerly obtained from a d-c Edison system or private generating plant.

HOT-CATHODE GAS-FILLED GRID-CONTROLLED TUBES—THYRATRONS

The control action of this type differs from the high-vacuum type in that only the start of the discharge is controllable. They are particularly suitable for controlling currents of a few amperes from a-c circuits. Their ability to control by cycles of the a-c supply leads to a number of valuable applications.

One of the earliest commercial applications for this type of tube was for the control of the illumination from incandescent lamps used in theaters and decorative lighting. In this application they functioned as controlled rectifiers to supply a variable direct current to saturation reactors. These latter functioned as variable reactors in series with the groups of lamps.

Within the past few years, applications have fallen largely into certain classes:

(*a*). Rectifiers to supply variable voltage or current from an a-c source of supply. This combination is employed to control d-c motors, field excitation of generators, and various electromagnetic devices.

(*b*). Inverters to supply either constant or variable-frequency a-c power (up to a limit of a few hundred cycles) from a d-c supply. As a variation of this the same general principle may be used for frequency changing.

(*c*). The use of a pair of tubes connected "back-to-back" so that in combination they pass alternating current. This gives a circuit element that not only acts as a contactor but by phase control of the grid voltage permits variation of the current passed. These tubes are so used in some welding control circuits where too large currents are not involved.

During recent years there has been a trend toward the use of inert gases, such as argon, neon, or xenon, to replace mercury vapor. This gives this class of tubes a freedom from ambient temperature effects that are sometimes troublesome with the use of mercury-vapor tubes. They are, however, not usable for peak inverse voltages up in the thousands as in the case of mercury vapor tubes. For small tubes to handle fractions of an ampere, the inert gas content also allows operation as an inverter up to thousands of cycles.

COLD-CATHODE GLOW-DISCHARGE TUBES

These are particularly applicable where filament operating power is not available and where ample control voltage can be employed. These tubes are often equipped with control electrodes. They are characterized by a higher voltage drop than the hot-cathode or pool type of gas-content tube. Also the current-carrying capacities are limited to a fraction of an ampere average current except that currents up to a hundred amperes or more can be carried for very short periods of time.

The two-electrode form has a number of applications that may be classified as follows:

(*a*). As a discharge tube to break down at some abnormally high voltage and thus act as a circuit protective device.

(*b*). As a voltage regulating device to place across a circuit. This use results from the characteristic of such a tube, with proper design, to pass a wide range of currents with a nearly constant voltage.

(*c*). As a negative-resistance element to generate oscillations by the relaxation circuit principle.

(*d*). As a rectifier based on the dissimilarity of the two electrodes.

(*e*). To produce light in accordance with the pulses of current through the tube. The light produced may be extremely intense for a very short time as for stroboscopic work or modulated in accordance with a variable current intensity or frequency.

When one or more control electrodes are added, the characteristics of a relay are gained. The applications listed above are retained and in some cases their scope extended. To date the three-electrode form has largely found its usefulness in the communication field but has wide relay possibilities in industry as it becomes better known and further developed.

PHOTOELECTRIC TUBE

In industry the photoelectric tube is performing many functions not possible by other means. In addition it is becoming an important agent in eliminating routine human effort. In combination with an amplifying tube, it is finding its place in applications where the eye and the hand are needed but not the brain.

During the past ten years, photoelectric-tube applications in great numbers have been made and, due to their apparent news value, widely publicized. Development of the photoelectric tubes themselves has been along the lines of smaller size, greater sensitivity, selective response in the spectrum, and novel mechanical designs for special applications. Lowered cost has also been helpful in extending their use.

Their applications may be grouped into three general classes:

(*a*). Applications in which a light beam, when interrupted or established, actuates a photoelectric relay. Examples of this are sorting, counting, door opening, hole detection, alarm systems, safety devices, and miscellaneous control jobs in industry.

(*b*). Applications where the tube and its accessories are actuated by variation in the amount of light falling upon it. Examples of this are smoke detection, check on turbidity of solutions, photometry and radiation measurement.

(*c*). Applications utilizing the difference in response of photoelectric tubes to light from different parts of the spectrum either directly or by the addition of filters.

Photoelectric tubes may be grouped according to the combination of features they employ. These classifications are:

(*a*). High-vacuum or gas-filled to increase their sensitivity.

(*b*). Nature of photoemissive surface which controls sensitivity and response to different parts of spectrum including the ultraviolet.

(*c*). Design and composition of bulb to transmit or restrict light flux from different parts of the spectrum to the photoemissive surface.

(*d*). Variations in mechanical design to adapt the photoelectric tube to special uses involving size, nature of base and direction, and degree of solid angle from which radiation reaches the photoemissive surface.

Existing photoelectric tubes have various combinations of these features.

Photovoltaic cells and selenium cells have not been considered within the scope of this review.

POOL TUBES—IGNITRONS

The outstanding characteristic of the pool cathode is its ability to pass very heavy currents—thousands of amperes. The addition of the ignitor gives the pool tube control characteristics. By phase control, voltage and current regulation are obtained and, by cycle control, short-time switching functions.

For a considerable number of years, preceding about 1933, the sealed-off pool type of tube had been slowly experiencing a decline in usefulness. Its chief applications were battery charging and high-voltage rectification for series arc lamps for street lighting. These were not growing applications. Then two new developments appeared which changed this picture completely. One was the ignitron and the other was the sealed steel envelope. The first solved the starting problem and gave the pool type the equivalent of grid control. The latter made large tubes and water-cooling practical and the tubes more acceptable to industry.

Since 1933 the use of pool tubes has grown steadily. Most of this growth has been in the welding control field where the tube's ability to carry very heavy peak currents has been an all important factor. The use of the sealed-off steel envelope ignitron for power conversion rectifiers for outputs between 75 and 350 kw has begun and appears to be a promising field.

CATHODE-RAY TUBES

In industry the use of a fine beam of electrons to produce and control a light spot on a fluorescent screen for oscillographic purposes is most common. These tubes can also be used for various forms of indicators.

For many years cathode-ray-tube oscillographs were considered as laboratory devices only but now they are commonly employed by electrical engineers and are necessities for many measurement problems. A better understanding of them, together with better-designed equipment and lowered cost, have been the chief contributions.

IT IS interesting to recall that this art is less than a century old[1] and that the early experimenters[2] actually worked in the frequency range now called "hyper frequencies."

The same basic principles are used at power frequencies and radio frequencies in the measurement art but the different techniques and nomenclatures often obscure this fact. These differences have arisen because the magnitudes of the fundamental quantities usually are widely separated. As the frequency is increased, the circuit usually changes markedly[3] since elements which are negligible at one frequency often become important in the new range. Size, design, and required accuracy also affect measurement problems.

It is the purpose of this paper to discuss the more common measurement problems at radio frequencies and to give a résumé of the status of this rapidly growing art.

Measurements of Voltage

The primary standards of voltage at radio frequencies are actually the usual d-c standards, and measurements are made by means of transfer instruments. The most popular instrument is the vacuum-tube voltmeter[4] which is available in forms ranging from the simple diode rectifier to a multitube inverse-feedback amplifier. All forms have the following characteristics in common: high input resistance, 0.25 to 10 megohms; low input capacitance, 1.5 to 30 micromicrofarads; response proportional to peak or average value, depending upon design; flat frequency response over the range for which they are designed, and they require a power supply. Because some forms of this instrument are so reliable and versatile, it is really no problem to measure radio-frequency voltages for a wide variety of conditions. The problem of obtaining a voltage measurement without affecting the voltage being measured is more common at radio frequencies than it is at power frequencies. The acorn-type vacuum tube is generally useful when this problem is encountered because of its small size and good electrical characteristics. Even under conditions which require that the small capacitance of this tube be compensated for, good measurements have been obtained. In fact, with proper technique, the acorn diode has given satisfactory operation at 300 megacycles per second. Conditions sometimes require that the diode voltmeter be built into the circuit[5] to avoid the errors which would result from moving even such a small device from one part of the circuit to another.

The vacuum thermocouple[6] is also a useful transfer device at radio frequencies because of the following characteristics: small frequency corrections, one calibrated on direct current has a correction less than one per cent at 100 megacycles per second; response to effective value regardless of wave shape; small size; and it is a passive network, primarily resistive. In addition, there is the cathode-ray tube which is rapidly gaining favor because it gives information as to wave form and frequency as well as magnitude. At present, it is much more expensive and more difficult to use than the other devices.

The radio engineer is often concerned with the microvolt, but none of these instruments is sufficiently sensitive to measure such small voltages so indirect means are employed to effect these measurements. A common way is by comparison with a voltage obtained by attenuating a voltage of the order of one volt by known amounts.[7] Another way to obtain microvolts is to generate them with a microvolt generator or second harmonic generator.[8] Figure 1 shows one form of the microvolt generator, and figure 2 is a schematic diagram of it. It is a full-wave rectifier so connected that the usually unwanted ripple current is used to generate a known voltage across the known impedance, *Z*. It depends upon the fact that if the tube characteristics are square law, the only output will be at twice the frequency of the input voltage and the peak value of this output

---

Paper 40-113, recommended by the AIEE joint subcommittee on electronics, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 22, 1940; made available for preprinting June 3, 1940.

HARRY R. MEAHL, P. C. MICHEL, M. W. SCHELDORF, and T. M. DICKINSON are all in the general engineering laboratory, General Electric Company, Schenectady, N. Y.

1. For all numbered references, see list at end of paper.

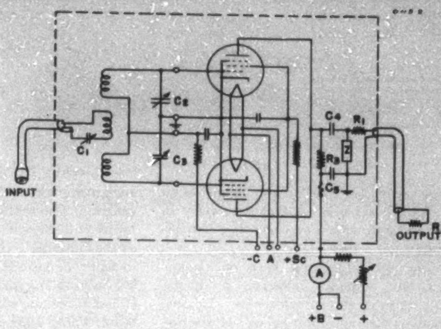

Figure 2. Schematic diagram of microvolt generator

current will be equal to the change in direct current in the plate circuit. When the tube characteristics depart from the square law, higher-order even harmonic currents are generated. It has been found practical to use the sixth harmonic. The essential fact is that no fundamental or odd harmonics are present and the radio-frequency current is indicated by a d-c microammeter.

When special problems arise, such as measuring 0.1 microvolt, which cannot be readily solved by either of the methods described, it is usually wise to refer to the work of Faraday, Maxwell, Hertz, and other pioneers. A mutual-inductance attenuator based on Maxwell's formula[9] and tested at high level was found easy to construct, test, and use to obtain voltages of the order of 0.1 microvolt at 40 megacycles per second.

The problem of measuring high voltages at radio frequencies is usually solved by using some form of multiplier with a moderate-voltage instrument as it is at power frequencies. The problem of designing the multiplier has no satisfactory general solution, but when capacitance dividers cannot be used, a tuned circuit or a quarter-wave section of transmission line may provide the solution.

The problem of inventing a practical standard of voltage at radio frequencies is fascinating and tantalizing. The phenomenon of resonance potential[10] in gases appears to have promise. A tube in which this phenomenon was observed is shown in figure 3. It consists of an anode and cathode sealed into a tube along with a drop of mercury and a coating of zinc sulphide. The anode is like the grid of an ordinary vacuum tube so that many of the electrons will go beyond it to strike mercury atoms. Those electrons having an acceleration of 4.87 volts cause radiation at a wave length of 2,537 angstrom units and this radiation is made visible by the fluorescence of the zinc sulphide. The problem remaining is to get precise correlation between the impressed voltage and the resonance potential. There must be a way to harness the electron.

Figure 1. Microvolt generator with indicator

Measurement of Current

The primary standard of current at radio frequencies is the oscillating-ring type of electrodynamic ammeter,[11] figure 4. Although unconventional in its method of indication, the oscillating-ring type of electrodynamic ammeter is simple. It is essentially a metal ring, free to rotate about a diameter, and immersed in an electromagnetic field produced by the current being measured. The field tends to orient the plane of the ring parallel to the flux lines with a torque proportional to the mean square current and to the small angular displacements of the ring's plane from this torque node. Therefore, if the ring is mechanically displaced and then released, it oscillates about the torque node, until damping brings it to rest, with a frequency of torsional oscillation proportional to the rms current. To obtain the value of a current, then, instead of noting the deflection of a pointer on a scale, the observer determines the mechanical frequency, F_m, of oscillation of the ring.

The actual measurement required for each determination is that of time, a fundamental measurement which can be made with great accuracy. Mathematically, the high-frequency current is given by the equation,

$$I=\left(\frac{2\pi\sqrt{JL}}{m}\right)F_m$$

where J, L, and m, are the ring's moment of inertia, inductance, and coefficient of mutual inductance with the exciter and are calculable from measurements of lengths and mass which need be made but once for the instrument. Since the fundamental measurements of length, mass, and time suffice for the determination of current in this instrument, it is a primary standard. That the required measurements of length, mass, and time can be made, and the necessary computation carried out, with accuracy, has been demonstrated by checking several different designs of vibrating-ring electrodynamic instruments against thermocouple ammeters at frequencies below the thermal error range of the latter.

As to structural details of this type of instrument, the exciter or current-carrying circuit, in whose field the ring is placed, is not restricted to any one form. For example, a single circular loop has been found useful for low currents and a single toroidal turn (figure 4) for large currents. In any case, its form does not require high inductance, nor does its function require an energy-consuming heating effect. Neither is large shunt capacitance, inherent in the temperature equalizing terminals of thermocouples, at all necessary.

The support for the ring may be a simple fiber suspension, or jeweled bearing for greater sturdiness.

The determination of the mechanical frequency of the ring's oscillation may be done quite closely by an observer with a

Figure 3. Critical-voltage tube

stop watch, or with greater precision by a light beam and photoelectric relay in conjunction with a two-pen tape chronograph and a time standard.

The oscillating-ring type of electrodynamic ammeter possesses a unique combination of characteristics. In contrast to the deflection types[12] of electrodynamic instruments, its impedance is independent of current, and it is not subject to loss of precision nor to limitation on maximum current by a cramped scale. As in other electrodynamic ammeters for high frequency, the effect upon its indication, produced by raising the frequency of the current, is calculable and small. In contrast to the effect in thermal ammeters, it decreases with increasing frequency. This follows from the fact that whereas thermal ammeters depend upon effective resistance which continues to increase with frequency, electrodynamic instruments depend upon flux linkages or inductance which approaches a fixed limit as frequency is raised. For example, in a conventional five-ampere thermocouple, the change in indication was calculated to be 1.6 per cent between 0.5 and 5.0 megacycles, and over 40 per cent between 5 and 50 megacycles; whereas in one electrodynamic instrument used, the corresponding figures were 0.77 per cent between 0.5 and 5 megacycles, and only 0.25 per cent between 5 and 50 megacycles.

A secondary standard of current at high frequencies, like one at power frequencies, should be capable of insertion in a circuit without seriously affecting the operation of either the circuit or the instrument. Furthermore, essentially all the radio-frequency current led to the "high" terminal should traverse the actuating element, and no indication should be had from strong surrounding fields. It is also desirable that high-frequency error in the actuating element be minimized.

The design of a low-impedance thermocouple-type ammeter indicates the methods applied to meet these requirements. In this low-impedance design, the actuating element or heater is a thin flat ribbon doubled back on itself with a thin mica separator between its inner surfaces. In order to preserve the advantages of minimum inductance and negligible stray fields inherent in this type of heater, its supporting studs are made short and concentric. The center stud, having its external end flattened and drilled to serve as the ammeter's "high" terminal, visible in figure 5, intrudes through an insulating bushing in a small shallow cup so that it makes contact with one flat end of the heater whose other end, opposite the mica separator, is mounted on the center of the cup's bottom. The cup, shown removed from the ammeter in figure 6, is recessed in the ammeter's back plate which itself serves as the external "low" terminal, seen in figure 5. The shielding effect of this concentric "low" terminal is continued about the miniature d-c instrument by the small contiguous metallic case and scale plate.

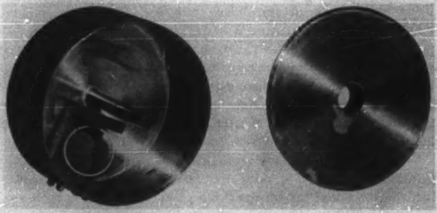

Figure 4. High-frequency electrodynamic ammeter

The effect on performance at high frequencies, which the above features of design have produced in the low-impedance thermocouple-type ammeters, is indicated by the results of comparative tests such as those described below.

For example, two conventional "high-frequency design" thermocouple ammeters when placed in series, read alike at 32 megacycles, one per cent different at 42 megacycles, and three per cent different at 52 megacycles; but these same instruments when individually placed in series with the low-impedance type instrument, with the latter in the "low" side of the circuit, each read the same as the low-impedance ammeter.

A further indication of the low impedance of this type of instrument is given by the fact that when applied as a series resonance indicator in a conventional wavemeter circuit, it allowed extension of the top frequency from about 150 to 360 megacycles at the same time permitting the use of a larger inductance loop. The wavemeter[13] smoothly covered a band from 160 to 360 megacycles, with a capacitor of 25 micromicrofarads maximum capacitance and an inductance comprising slightly more than one turn one inch in diameter in addition to the capacitor leads. The inductance of the instrument is 0.005 microhenry.

The effectiveness of its shielding has been demonstrated in a test in which a number of thermocouple-type ammeters, including both the low-impedance and conventional types, were placed directly in radio-frequency fields. Between 15 and 90 megacycles, the ammeters were placed within one-quarter inch of the tank coil of a 50-watt oscillator, and between 260 and 380 megacycles they were placed in the maximum field of the tank lines of a line-controlled 15-watt oscillator. Although conventional-design ammeters during these exposures, with no current actually applied, gave readings ranging from zero at lower frequencies to more than full scale at higher frequencies, the low-impedance type instruments under the same conditions uniformly maintained a reading of zero.

Thus, when the low-impedance thermocouple-type ammeter is inserted in a circuit, it introduces a minimum of reaction on the circuit, remains unaffected by surrounding fields, and indicates no more nor less than the current entering its "high" terminal. In addition to the demonstration of these characteristics prerequisite in a secondary standard of high-frequency current, further tests have shown that skin-effect error at high frequencies in the doubled-ribbon heater has been greatly reduced below that found in the solid-wire type of heater.

The concepts of Faraday are particularly helpful in problems of measuring current at high frequencies, because when high-frequency currents of any size flow, the fact that the energy is in the fields becomes apparent. For example, men standing six to eight feet away from a ten-kilowatt oscillator operating at 75 megacycles have felt their ankles get warm. This approach to a current-measuring problem leads to correct application of available instruments because the way high-frequency currents divide in a particular circuit becomes reasonable when the fields are considered. When a spacer is thought of as a dielectric medium rather than as an insulator, the "mysterious" loss of current in a circuit becomes an expected occurrence.

Measurements of Frequency

A primary standard of frequency is an oscillator whose rate is substantially constant when determined by counting the number of oscillations and dividing it by the time taken to produce them. The unit of frequency is, therefore, based on the standard second which is 1/86,400 of the mean solar day or 1/86,164.100 of the sidereal day. The National Bureau of Standards maintains several primary standards of frequency and makes some of them available for general use by means of standard frequency transmissions over station WWV, Beltsville, Md. Many laboratories maintain primary standards of frequency by using the WWV standard frequency transmissions and the United States Naval Observatory time signal[14] transmissions to check them. The counting of radio-frequency oscillations may be accomplished by means of a combination of electronic counter circuits and a mechanical counter. The multivibrator[15] or relaxation oscillator is commonly used for the electronic counter and a synchronous-motor clock for the mechanical counter. Rates constant to one part in ten million are commonly obtained by means of quartz-crystal-controlled oscillators operating at 100,000 cycles per second.

In many cases, a signal from the oscillator or transmitter whose frequency is to be determined can be brought to the primary standard and the measurement made by direct comparison. When this is not practical and an accuracy of 0.1 per cent is acceptable, the common absorption-type wavemeter consisting of an inductor and a capacitor connected in series can be used. The operation of this device depends upon the following relation between frequency, inductance, and capacitance:

$$f = \frac{1}{2\pi\sqrt{LC}}$$

When greater accuracy is required, some form of the heterodyne wavemeter may be used. The heterodyne wavemeter is a calibrated oscillator which can be tuned to the frequency of the unknown signal with great accuracy by one of the beat note methods. When a quartz-crystal-controlled oscillator is used to check the calibration of the heterodyne oscillator, an accuracy of 0.001 per cent can be obtained.

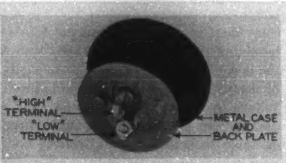

Figure 5. Low-impedance thermocouple ammeter (rear)

The problem of measuring higher and higher frequencies stays with us as the art progresses. In most cases, the first need is a suitable receiver for the unknown signal and the problem remaining is to set a high-frequency oscillator accurately on a harmonic of the standard. For example, adjust a 1,000-kc crystal to the tenth harmonic of the 100,000-cycles-per-second standard, then set a 10,000-kc crystal oscillator on the tenth harmonic of the 1,000-kc oscillator. This process can be carried as far as necessary to provide guide posts in the upper frequency spectra.

Since frequency can be measured so accurately, it is highly desirable to be able to use it as the indicator when measuring other quantities. For example, an excellent way to measure small changes of capacitance[16] is to put the capacitor in an oscillating circuit so that these changes cause changes in frequency which can be monitored continuously and accurately.

Measurements of Power Factor and Dielectric Constant of Materials

It is as important to know the power factor and dielectric constant of an insulating material used in a radio transmitter as it is to know the power factor of a load on a power line. The power factor of a material is the cosine of the angle whose cotangent is the ratio of conductance to susceptance in the sample when it is used as the main dielectric in a two-electrode capacitor. This is based on representing the sample by a pure resistance in parallel with a pure capacitance. It may also be represented by a resistance in series with a capacitance and then the power factor is the cosine of the angle whose cotangent is the ratio of resistance to reactance.

Power-factor standards can be made of disks of pure, clear fused quartz because the power factor is 0.0002 from 1 to 3,000 megacycles per second. The bases of this statement are a determination at 3,000 megacycles by W. C. Hahn, engineering general department, the work of Von Lothar Rohde[17] at 200 and 500 megacycles, and the work of this laboratory.

There are many ways[18] of measuring the power factor of a material at frequencies less than one megacycle per second. Some of the circuits available are: parallel bridge, series bridge, resistance variation, substitution, and reactance variation.

At frequencies above one megacycle, the reactance-variation[19] type of circuit has been popular. This popularity probably resulted from the fact that power factor is determined by measuring capacitances, changes of capacitance, and ratios of voltages. Variable capacitance of known value is easier to obtain than variable resistance at frequencies above one megacycle. The procedure is to measure the width of the resonance curve for a certain ratio of voltage at resonance to voltage off resonance with the sample capacitor tuning the resonant circuit and repeat this with an air capacitor in place of the sample. These data are sufficient for two separate circuit-resistance determinations and, therefore, for the effect of the sample on the circuit. Since the measurement of power factor is a resistance measurement, the following factors in addition to those in the measuring equipment are important: the size and shape of the sample; the size, shape, and material of the electrodes; and the method of applying the electrodes to the sample. The size and shape of the sample are major determining factors of the capacitance. If this capacitance is made small compared to the inherent capacitance of the measuring circuit, it will obviously become difficult to determine the effect of inserting the sample. On the other hand, if it is made large, its reactance will approach that of the residual inductance in the measuring equipment and will cause resonance effects and consequent inconsistent operation. The size and shape of

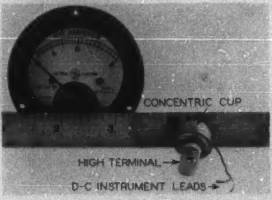

Figure 6. Low-impedance thermocouple ammeter (front)

the electrodes also affect the capacitance, but the effective resistance of the electrodes is often the more important factor.

Because there are so many possible sources of error, it is good to have a clear fused-quartz standard sample to test the over-all operation of any power-factor measuring equipment.

The dielectric constant of a material is the ratio of the capacitance of a pair of electrodes with the dielectric between them to their capacitance for the same spacing in a vacuum. It is necessary to choose the electrode geometry properly[20] to allow accurate determination of the dielectric constant when the sample size is fixed. The capacitance of the sample is usually a by-product of the power-factor measurement procedure.

Measurements of Impedance

One way to determine impedance is to measure the current through and the voltage across the unknown impedance and calculate the ratio of E to I. Even at power frequencies, it is not convenient to use this method and at radio frequencies it is seldom convenient to use. One reason for this is that one-inch leads are the same part of a wave length at 63.36 megacycles per second as one-mile leads are at 1,000 cycles per second. It is hard to overemphasize the need for short leads from the measuring equipment to the unknown impedance.

In addition to requiring short leads, the problems which have arisen frequently since the advent of television have required that the measuring equipment be portable where portable means that the user can carry it up an antenna tower and use it at the top. An instrument for this service in the 40 to 70 megacycles per second frequency range is shown in figure 7 and a schematic diagram is shown in figure 8. It will be noticed that provision has been made to obtain short leads. At the same time, the measuring circuit was shielded from the oscillator and from external fields by placing it in a separate metal compartment, by providing Faraday screens between the oscillator coil and one coupling coil and between the other coupling coil and the measuring circuit coil, and by using a common ground.

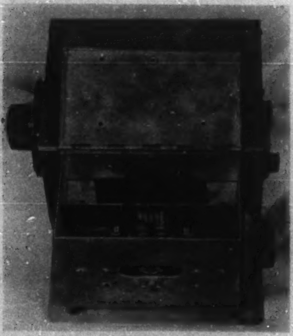

Figure 7. Portable impedance measuring instrument

The measuring circuit is a coil and a capacitor so arranged that either balanced or single-ended impedances can be measured by the reactance-variation method. The parallel tuned circuit has been so arranged that the unknown can be connected in series with the coil and consequently low values of impedance can be measured. The usual parallel connection of the unknown is also provided for high values of the unknown. The procedure is to determine the circuit constants with and without the unknown connected in terms of capacitance, change of capacitance, and voltage ratios. The differences between the two resulting sets of susceptance and conductance values are the constants of the unknown impedance.

This instrument was used in the installation of the transmission lines and antenna of General Electric television station W2XB in band 3 (66 to 72 megacycles).

It is often necessary to measure the inherent inductance in low-value resistors. One way to measure these small inductances is to use the microvolt generator.

The procedure is to insert a resistor, R_1, as Z and measure the current, i_1, which causes a certain output at frequency, f_1; replace R_1 by a different resistor, R_2, and find the current which causes the same output; repeat this procedure at another frequency, f_2, and solve the resulting simultaneous equations:

$$i_1\sqrt{R_1^2+(2\pi f_1L_1)^2}=i_2\sqrt{R_2^2+(2\pi f_1L_2)^2}$$

$$i_1^1\sqrt{R_1^2+(2\pi f_2L_1)^2}=i_2^1\sqrt{R_2^2+(2\pi f_2L_2)^2}$$

In a particular case, a two-ohm and a ten-ohm resistor were used at 25 and at 40 megacycles. The inductance of the two-ohm resistor was 0.016×10^{-6} henry. The impedance of the two-ohm resistor is, therefore, 3.20 ohms at 25 megacycles and the necessity for determining inherent inductance in low-value resistors is evident.

Measurements of Transmission Line Characteristics

In television transmitting systems as in other radio transmitting systems, it is usually impractical to locate the transmitter unit adjacent to the antenna. A transmission line is employed to connect these parts, and for the wide-frequency-band operation needed in television communication, the transmission line must have quite definite characteristics.

Physically such a transmission line usually consists of straight sections of concentric tubes with spaced low-loss beads for insulation. Sections are joined at corners by means of junction boxes and the inner conductor is supported in long vertical runs by means of an anchor joint. To secure proper performance of the transmission line, it is necessary to compensate for the electrical disturbances produced by these junction boxes and anchor joints. It is also necessary to match the antenna circuit to the transmission line much more closely than was commonly practiced in communication or broadcast transmitter systems. For these reasons, it is desirable to measure the characteristic impedance of the line and to determine its frequency characteristic with compensating elements added at the required positions.

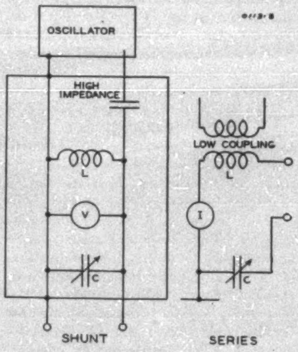

Figure 8. Schematic diagram of measuring instrument

The reactance-variation type impedance-measuring instrument already described can be used to measure the characteristic impedance of the line, but it is not convenient to use this instrument for determining the frequency characteristic of the line. This may be done more easily by measuring the ratio of output to input voltage over the operating range of frequency. In practice, it has been found desirable to hold the input voltage constant which makes the output voltmeter indication proportional to the ratio wanted.

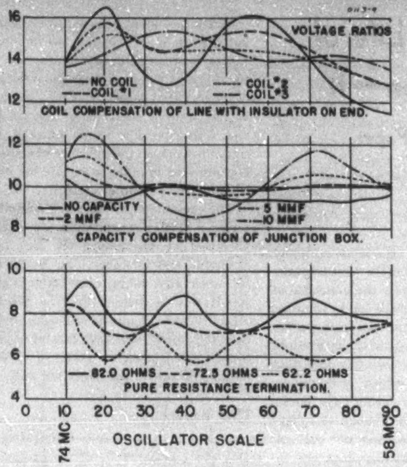

Figure 9. Experimental voltage-ratio curves

It is necessary that the ratio of output to input voltage remain practically constant over the operating-frequency range and desirable that it remain so over a wider range to give a safety factor. The information given in plots of voltage ratio versus frequency is shown in figure 9. The lowest set of curves shows that resistance terminations can be readily identified as lower or higher than characteristic impedance of the line. The middle set shows how changes of capacity at a junction box caused marked and easily recognized changes in the ratio curves also. The top set demonstrates the case of coil compensation.

When this method of measuring transmission-line characteristics is used, it is desirable to start with a short section and to add junction boxes, other sections, and anchor joints one at a time. If several things are added at once, the voltage-ratio curves become difficult to interpret; but if one thing is added at a time, the curves are as easy to interpret as those shown. A mathematical treatment of these relations is in the literature.[21]

That complete transmission characteristics over wide frequency ranges can be secured by properly using a pair of diode voltmeters is encouraging.

Conclusions

How basic principles are used in making measurements at radio frequencies has been shown in a number of cases.

Something of the range of the subject has been suggested by the diode voltmeter and the "critical voltage" tube.

A primary standard of current at high frequencies has been described.

A new low-impedance thermocouple ammeter has been presented.

Clear fused quartz has been proposed as a standard of power factor in the 1 to 3,000 megacycle-per-second frequency range.

A typical technique of making measurements at radio frequencies has been disclosed by the description of the "reactance-variation" method of measuring impedance.

It is hoped that the material presented will prove informative to engineers not directly connected with radio-frequency measurement work as well as to those in it.

The Dielectric Strength and Life of Impregnated-Paper Insulation—II

The Influence of the Thickness of the Paper

J. B. WHITEHEAD
FELLOW AIEE

THE peculiarly severe conditions imposed by manufacture, transportation, installation, and operation of high-voltage cables have emphasized the importance that full attention be paid to all physical properties of the insulation, especially those relating to permanence of mechanical structure and of high insulating properties. The requirement of wide flexibility is at the root of the present method of applying the paper insulation in spiral tape form in successive layers.

Mechanical flexibility and high dielectric strength do not always go hand in hand. They do so to an astonishing degree in the case of impregnated paper. However, with the available materials it is not always possible to retain at the same time the maximum of flexibility and the maximum of dielectric strength and stability. Consequently in cable design, in order to meet the special requirements of particular cable installations, it is necessary to make such selection of the paper to be used as will ensure the optimum combination of flexibility and dielectric strength. Carefully prepared wood-pulp paper with low content of electrolytic impurity is now used almost exclusively for the type of insulation in question. It is available over fairly wide ranges of density and thickness, as determined largely by experience in manufacture and usage over the past 20 years or more. It is within these ranges of paper structure that the cable engineer finds the possibility of selecting papers for a very wide range of type of cable and conditions of service. The fact that impregnated-paper cables are giving highly satisfactory service for large blocks of power in the highest range of values of voltage is an indication not only of the remarkable insulating properties of this type of insulation, but also of the resourcefulness and persistence of cable engineers in experimental study and manufacturing skill.

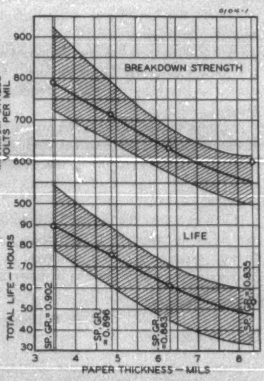

Figure 1. Breakdown strength and life as function of paper thickness

In a related paper,[1] the present author has reported the results of a study of the influence of a variation of the density of the paper on dielectric strength as determined in a fixed program of accelerated voltage-time tests. The results of the study were at some variance with commonly accepted ideas[2] as to the influence of paper density on dielectric strength. They confirm the suggestion that has been made from time to time[3] that proper consideration must be given to the laminated form of construction, to the open spaces between successive tapes, and to the different values of dielectric constant of impregnated paper and of oil. In view of the positive character of the results and of their possible bearing on cable design, the work on the influence of density is continuing in order to explore the possible influence of other variables.

The present paper describes a similar series of studies on the influence of the thickness of the paper on dielectric strength and stability, as indicated by accelerated voltage-time tests. Here too it will be found that the results are of definite character and again indicate the importance that careful attention be given to the variations in the internal structure of the insulation wall.

The Papers

High-grade cellulose paper for cable manufacture is available in the range of thickness 0.0035 to 0.008 inch (3.5 to 8 mils, 0.0089 to 0.02025 centimeter). For the present studies four thicknesses of approximately 0.0035, 0.0048, 0.0063, and 0.00835 inch were used. The papers were supplied by a well-known manufacturer in the form of tapes one inch wide. It was intended that the density of the paper structure be the same for each thickness. As measured, however, the density of the 8-mil paper fell slightly below the others (see table I). We refer to the papers briefly as having nominal thicknesses 3, 5, 6, and 8 mils respectively.

The Test Specimens

The test specimens were made by wrapping the paper tapes on smooth brass tubes with $33^1/_3$ per cent and $66^2/_3$ per cent overlay with a butt spacing of the tapes of approximately $^1/_{64}$ inch (0.00397 centimeter). The number of layers of each thickness of paper was so chosen as to give approximately the same over-all thickness of all test specimens. (See table I.)

Nine identical specimens were constructed from each thickness of paper. They were dried and impregnated in groups of three. All specimens were impregnated with a light oil as used for oil-filled cables by American manufacturers.

Further details as to the measuring and guard electrodes, reinforced ends, etc., of the test specimens, of the physical characteristics of the oil, and of the methods of drying and impregnation will be found in earlier papers.[4]

Paper 40-104, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 5, 1940; made available for preprinting May 6, 1940.

J. B. Whitehead is professor of electrical engineering and director of the school of engineering, The Johns Hopkins University, Baltimore, Md.

This research, carried out in the laboratories of the School of Engineering of The Johns Hopkins University is a project of the Engineering Foundation with the sponsorship of the AIEE. Grateful acknowledgment is made of the support and advice frequently furnished by both these bodies, and particularly by members of the advisory committee appointed by the AIEE to follow the course of the work. Cordial thanks are also extended to the Union Mills Paper Company, The Sun Oil Company, the Locke Insulator Corporation, and to the Insulated Power Cable Engineers Association for material and other forms of assistance furnished. Special thanks are due Research Assistant C. O. Newman, to whose skill and devotion much of the success of the work is due.

[1] **For all numbered references, see list at end of paper.**

Experimental Method

All tests were made on single specimens immersed in the impregnating oil in a bath enclosed in a thermally insulated box with automatic temperature control.[5] The air pressure in the test box was that of the atmosphere. The temperature for all tests was 40 degrees centigrade.

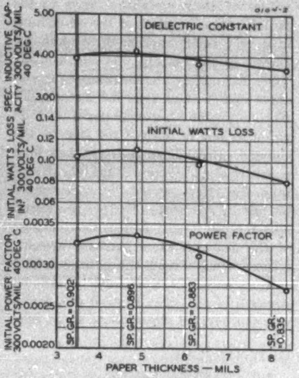

Figure 2. Dielectric constant, dielectric loss, and power factor as function of paper thickness

Life and Breakdown Tests. The accelerated voltage-time tests started at a voltage to give an average stress of 400 volts per mil on the specimen and the test voltage was increased by 3.12 per cent every four hours, thus giving a geometric increase such as to bring the stress to 700 volts per mil within three days. Under this program the range of life of all specimens tested was from two to four days.

Power Factor and Capacitance. Power factor and capacitance were measured over the range 100 to 400 volts per mil on a high-voltage Schering bridge[6] at the beginning of the voltage-time test and at 12-hour intervals.

Conductance. The long-time d-c conductance of the dry paper specimen was measured at 1,500 volts and 105 degrees centigrade before impregnation, and of the impregnated specimen at 60 degrees centigrade immediately following impregnation.

Experimental Results

The results of the accelerated voltage-time and breakdown tests on the three-mil paper are given in table I. They are typical of the results on the other thicknesses of paper, for which the average values only are given in the table. Using the average values of breakdown stress, as given in table I, the results on breakdown strength and accelerated voltage-time and other electrical properties are plotted in figures 1 and 2. The shaded areas represent the extreme limits of the spread of the test values. The average spread is substantially lower as seen in table I.

The results indicate that with increasing thickness of the paper, there are marked variations in all the electrical quantities, as well as the values of breakdown stress and life.

Breakdown Strength and Life. Both these quantities decrease with increasing thickness of paper, over the range studied. (See figure 1.) This similarity of behavior is a necessary consequence of the type of accelerated voltage-time test. Since the life run begins with a stress of 400 volts per mil, it happens that the percentage change in over-all duration of time (life to breakdown) is greater than that of voltage. The decrease in the average values of breakdown stress is from 788 to 602 volts per mil. This indicates a decrease in breakdown strength of something more than 25 per cent as between the three-mil and the eight-mil papers. This decrease would have been about 28 per cent if the specific gravity of the eight-mil paper had had the same value as that of the other papers. Discussion of these results and a probable explanation will be found in a later paragraph.

Dielectric Constant. Over the range of thickness studied there is a small decrease in the value of dielectric constant (see figure 2). This is apparently due to the slight decrease in density with increasing paper thickness. Corrected[1] for this variation, the value of the dielectric constant is very closely the same for all thicknesses.

Dielectric Loss and Power Factor. Both these quantities show a noticeable decrease in value with increasing paper thickness. Of the total change in power factor approximately 40 per cent may be attributed to the change in paper density.[1] The fraction of the total change

due to this cause in the case of the loss is approximately 30 per cent. Apparently, therefore, some factor other than density is playing a part in these decreases.

Oil Content. The oil content of the impregnated paper tape alone expressed as the ratio by weight of oil to paper is given in table I. It will be seen that the volume of oil absorbed increased approximately uniformly with increasing thickness of paper from the value 38.8 per cent for the three-mil, to 49.1 per cent for the eight-mil paper. This variation also is accounted for by the variation in paper density.

Type of Breakdown. All specimens were carefully examined after failure as to evidence of its beginning and cause. In the latter half of the work these studies were greatly facilitated by the use of a thyratron tube, relay, and rapid circuit breaker[6] for interruption of the primary circuit of the transformer. The operation of this device is so sensitive and rapid that not only is the usual burning attendant upon breakdown very greatly reduced, but in many cases the circuit is opened before the failure has extended further than two or three layers of paper. Further details of the operation of this equipment are given in the paper already referred to on the influence of the density of the paper on breakdown and life.[1]

Failures took place almost invariably under the central electrode of the test specimen and all failures have been of definitely radial type.

A clear indication of the foregoing studies on density, and of the present studies, is that most of the failures begin in the oil channels between successive turns of paper, most often at the central high-voltage electrode, sometimes in the center of the insulation wall, and in a few cases at the outer electrode. In a number of cases in which the specimen was dissected after the first two or three shots, the incipient failure was found to be confined to two or three layers. At one point the oil in a channel would be found to have become black, the blackening extending a short distance either way along the channel and along the edge of the paper. The next stage would be the puncture of one or perhaps two paper layers, but generally reaching the next oil channel on the same radius. Occasionally longitudinal tracking and tree patterns to adjacent channels were noticed, but these extended only a very short distance, probably because of the relatively thin total wall thickness. Evidence of initial blackening in oil spaces was also invariably noticed at the edges of the small holes in the central tubular conductor and outer lead-foil electrode drilled to facilitate drying and impregnation. However, the failure showed no preference for the edges of these holes. Invariably the central tubular conductor would be blackened under the full spiral length of the oil channel between the tape edges of the first layer, the remainder of the conductor remaining clean and bright.

Altogether the failures seem to be closely similar to those reported by Robinson[7] and Race,[8] both of whom find that the initial carbonization occurs next an electrode. However, several of our specimens have shown evidence that the initial seat of the trouble may be in the center of the insulation wall.

The interrupted failures and behavior described above are best observed in the thinner range of papers (see particularly results of the study of the influence of paper density[1]). In the present tests as the thickness increases, it is more and more difficult to limit the failure to a portion of the wall. Most of the failures above those in the three-mil paper have been through-failures with more pronounced burning, with less tendency to tree patterns and tracking and consequently with greater obscurity of the conditions surrounding initial failure.

Discussion of Results

Breakdown Strength and Life

The most probable explanation of the decrease of breakdown stress and life with increasing thickness of paper is the well-known fact that the breakdown strength of thin oil films decreases with increasing thickness. Our results indicate that the failures always start in the oil films between successive turns of paper tape. J. Sorge[9] reports a decrease of dielectric strength with increasing gap thickness, between approximately parallel planes, for xylol, benzene, and hexane, over a range of thickness 0.2 to 0.7 millimeter (8 to 28 mils). This is just outside our range of oil-channel thicknesses (3.5 to 8.0 mils). However, Sorge's curves are all pointing sharply upward at the lower values of gap. Other authors[10] report similar behavior.

Approximate computations[1] of the values of stress in the oil channels in our results in the increasing order of paper thickness are 1,506, 1,416, 1,170, 1,075 volts effective per mil. Naeher's[11] values for pure liquids and thicker layers mentioned above are from 1,700 to 1,200 volts per mil. His results on transformer oil and for gaps from 0.5 to 3 millimeters show a decrease of from 560 to 400 volts per mil. It will be seen, therefore, that our values are intermediate between those for the pure liquids of Sorge and those of Naeher for transformer oil, which was probably not so highly purified as the oil of our tests. In explanation of the above behavior, I suggest the presence of mobile ions in the oil which are greater in number with increasing thickness of oil channel. These ions, owing to the high values of their mobilities, pass to the radially opposite faces of the oil channel in a very small fraction of one-half the period of alternating 60-cycle voltage. They accumulate at the opposite faces as space charges and thus increase the potential gradient between paper and oil on either one or both of the faces of the channel. Breakdown begins at these high points of electric stress in the oil. Naturally the effect would be accentuated by minute filaments of paper projecting into the oil. With increasing thickness of the channel, more ions are present, greater values of space charge accumulate, and consequently a critical breakdown strength of the oil is reached at a lower value of over-all stress.

Dielectric Loss and Power Factor

These two quantities apparently decrease with increasing thickness of the paper, the former by about 20 per cent and the latter by about 15 per cent. The explanation is not entirely obvious. Only a portion of these decreases is accounted for by the variation in paper density. With increasing paper thickness, there are obviously fewer oil layers between paper tapes. The oil channels, however, apparently do not enter into the matter of loss in any considerable extent; first because the oil channels have the same total thickness for all thicknesses of paper; moreover, the volume of oil is a relatively small fraction of the total volume, and the loss per unit volume in oil is generally substantially less than that in the impregnated paper.

The losses in impregnated paper, qualitatively speaking, should vary in accordance with the laws for a Maxwell layer dielectric. This affords a very much better explanation of the results found. There are fewer oil layers with the thicker tapes and the barrier action to current flow is obviously greater in the thicker tapes. Thus the number of surface layers of charge at the surfaces of separation, the amount of dielectric absorption, and consequently the dielectric loss under alternating stress, are all lowered with increasing thickness of paper.

Summary and Conclusions

1. Accelerated voltage-time tests have been carried out on samples of impregnated-paper insulation with the thickness of the paper tape as a variable. Four thicknesses of nominal values, 3, 5, 6.5, and 8 mils, and all of approximately the same density, were studied. All specimens were impregnated with a very fluid insulating oil.

2. In accelerated voltage-time tests beginning at 400 volts per mil and with geometric increase of voltage at the rate of 3.12 per cent every four hours, the 60-cycle breakdown voltage was found to decrease with increasing paper thickness. Over the range of thickness mentioned, the decrease in breakdown voltage with increase of thickness was about 28 per cent. The decrease in life was approximately 45 per cent.

3 The failures almost invariably start in the oil channels between successive convolutions of the paper tape.

4. The maximum stress in the oil channels at breakdown, as computed from the dielectric constant of the oil, and the measured dielectric constant of the impregnated paper, decreased with increasing thickness over the range studied from 1,506 to 1,075 volts effective per mil. An explanation of this behavior is offered.

5. The dielectric constant of the impregnated paper is approximately constant over the range of thickness studied.

6. Power factor and dielectric loss decrease with increasing paper thickness, the former by about 30 per cent and the latter by about 20 per cent over the range of thickness studied. This behavior is explained qualitatively by the variation in interfacial polarization in accordance with Maxwell's theory.

Discussion

Discussion will be found in the 1940 annual Transactions volume and in the 1940 Supplement to Electrical Engineering—Transactions Section.

Computation of Accuracy of Current Transformers

A. T. SINKS
ASSOCIATE AIEE

WHILE the general principles of the operation of current transformers have been known for some time, and tests have provided much experimental data, the introduction of high-speed relaying, especially differential protection, required a greater knowledge of current-transformer performance than was necessary previously. It is the purpose of this paper to present a method of calculating the accuracy of current transformers.

Formulas for calculating leakage flux and leakage reactance in power transformers have been available for several years. Some good experimental work showing the effect of leakage on the flux densities of the core of current transformers was done by H. W. Price and C. K. Duff of the University of Toronto, and much study has been devoted to the magnetic properties of iron and other material, but little seems to have been done in applying the formulas of power transformers to current transformers, or in establishing the rules which govern the effect of leakage flux on the accuracy. Most of the information concerning current transformers has been derived by the experimental method of making ratio correction factor and phase-angle tests of models.

However, within recent years, a considerable amount of work and testing has been done at the West Lynn Works of the General Electric Company to obtain reliable information on the exciting currents of various magnetic materials over a wide range of flux density. This information made it possible to check methods of calculating the accuracy. The method of calculation here presented was developed largely on a theoretical basis from the fundamental principles involved making use in so far as possible of the well-established power-transformer formulas and was found to give results in very good agreement with the tested accuracy.

By using the method presented in this paper it becomes possible to calculate current-transformer performance from available experimental data without making and testing models. This makes it possible to design current transformers for specific application, or determine the suitability of an existing design without the cost of overcurrent ratio and phase-angle test. It is also very useful as a tool to the designer, because it enables him to compare several proposed designs, and select the best at less cost than by using experimental models and making tests.

Paper 40-89, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted November 8, 1939; made available for preprinting May 23, 1940.

A. T. Sinks is designing engineer, General Electric Company, Lynn, Mass.

In order to compute the accuracy of a current transformer it is first necessary to define the term "accuracy". This can best be done by defining the inverse of accuracy, that is, the error. Fundamentally, the error of a current transformer is the vector difference between the primary and secondary ampere turns. Now this difference is, by virtue of the relative position of the primary and secondary coils, the number of ampere turns acting on the magnetic circuit of the transformer and is, therefore, the exciting current of the transformer in ampere turns. Hence, the rather intangible expression "accuracy" upon analysis becomes simply the inverse of exciting current.

It is, therefore, the first purpose of the following analysis to determine the exciting current. Only a wound-type transformer with two coils, one inside the other, will be considered in detail, but the general principles for the most part apply to any type.

In the development of the formulas the following assumptions will be made:

1. The secondary coil is inside the primary, which is usually the case.

2. The leakage flux flows parallel to the axis of the coil.

3. Flux density is zero on the outside of the primary copper and inside of the secondary copper, and increases linearly to the edges of the space between the copper of the two coils, the density on the primary side of the space being $3.2N_2I_2/L_1$ lines, secondary side $3.2N_2I_2/L_2$ making a mean density in the space of $3.2(2N_2I_2)/(L_1+L_2)$ all values being expressed in English units* (see figure 1 for symbols). Although it is obvious that the assumption regarding the conformation of the magnetic field is not exactly true, these assumptions are conventionally made in calculating reactance of transformers and have been shown to give values in good agreement with test.

4. In the computation of exciting current the ampere turns required for the core joints will not be considered separately. This procedure is usually permissible, if, as in the computations here presented, the core data used are derived from tests on a core having approximately the same number of joints per inch as the core of the transformer under consideration and if the joints are symmetrically disposed on the core. In some cases where the joints all happen to be in regions of flux density much higher than that in the rest of the core it may be necessary to consider the joints separately if the densities are high. This can be done by determining the density at the joints from the equations hereafter presented and adding the necessary ampere turns for the joints to the exciting ampere turns required for the rest of the core. Except on cores having short magnetic circuits or cores made of very high permeability material good lapped joints will not take a very large per cent of the total exciting current required for the core at low flux densities but usually will at high densities.

Figure 2. Phase angles between secondary current and fluxes in different sections of core

5. Much the same statement holds with respect to grain direction for cores in which the flux path is in different directions relative to the grain of the iron in different sections of the core, as the exciting current is usually higher when the flux flows across the grain than when it flows parallel to the grain.

6. The exciting currents will be treated as vectors in adding the exciting current for the various sections of the core, although it is not strictly correct to represent them as such since they are not in general sinusoidal. Experience, however, indicates that the errors introduced by assuming them so are negligible except possibly at quite high flux densities where the wave form of the exciting current is badly distorted.

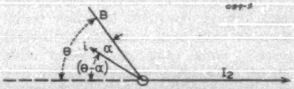

Figure 3. Vector diagram showing relation between flux density, exciting ampere turns, and secondary current for any particular core section

7. The magnitude of the leakage flux and its conformation are assumed to be dependent only upon the geometry of the apparatus, and the ampere turns in the coils, and are independent of the permeability of the magnetic core material. This assumption, of course, is valid only if the permeability of the core material is high relative to that of the air or other nonmagnetic media. Should the permeability of the core become quite low as the result of either a high overcurrent or a heavy burden which badly saturates the core, the configuration of the leakage flux may be altered, and its magnitude will no longer be strictly proportional to the ampere turns in the coils. This assumption limits the application of this method of analysis to conditions where the maximum magnetizing force in the core is about 300 ampere turns per inch or less.

8. It is also assumed in the analysis that with a sinusoidal primary current the secondary current will be a sine wave. For this assumption to be reasonable, it is necessary that the exciting current either be nearly sinusoidal or be a small per cent of the primary current. Actually the exciting current is almost never sinusoidal although it may be approximately so for the lower values of flux density; but it is usually, in good transformers, a small per cent of the load current. Therefore, the harmonics introduced by the exciting current are seldom of much consequence in the normal range of operation. However, here again, if due to either high overcurrent or a heavy burden, the core becomes saturated, the exciting-current wave form has large harmonics and the transformer error usually gets relatively large in which case the per cent of harmonics in the secondary current is likely to be appreciable.

Figure 4. Vector diagram of relation between primary and secondary ampere turns and total exciting ampere turns for core of a current transformer

If the harmonics thus introduced into the secondary current are large enough to be of concern, then a more precise and elaborate definition of accuracy is necessary as the ratio and phase-angle errors alone will no longer suffice to define completely the difference between the correct and the actual values of secondary current.

In figure 1 is shown a wound-type current transformer of a type which will be considered, and below it is a list of the principal symbols used. **Bold-face** type indicates a vector quantity, and all vectors will be referred to the secondary current as a base.

On the basis of the assumption relative to the distribution of leakage flux, the values of leakage flux are:

$$\Phi_{L2}=3.2\frac{N_2I_2}{2L_2}A_2 \qquad (1)$$

$$\Phi_{L0}=3.2\frac{N_2I_2}{L_1+L_2}2A_0 \qquad (2)$$

$$\Phi_{L1}=3.2\frac{N_2I_2}{2L_1}A_1 \qquad (3)$$

In order to determine the exciting current it is first necessary to establish the

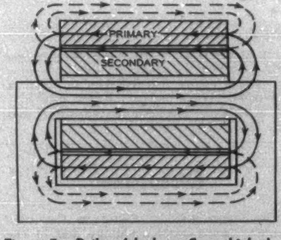

Figure 5. Paths of leakage flux which does not pass through secondary copper

---

* The factor 3.2 comes about as follows: For air using metric units flux density $B=H=0.4\pi NI$/cm lines per square centimeter. Therefore, in English units $B=0.4\pi NI$/in.×2.54 lines per square inch.

flux density or densities in the core. This can most readily be done by beginning with Φ_C. To find Φ_C it will be assumed that the fraction of Φ_{L2} which returns inside the secondary is Y and that the fraction of $(\Phi_{L1}+\Phi_{L0})$ returning inside the secondary is U. The fractions Y and U are involved in the calculation of Φ_C in two ways. In the first place, it is apparent that

$$\Phi_C=\Phi_M+Y\Phi_{L2}+U(\Phi_{L1}+\Phi_{L0})$$

In the second place Φ_M is related to E_{L2} and E_2 by the relation

$$E_2=-jK\Phi_M+E_{L2}$$

whence

$$\Phi_M=\frac{j}{K}E_2-\frac{j}{K}E_{L2}$$

and it is obvious that E_{L2} will be dependent on the values of Y and U. In the appendix it is shown that

$$E_{L2}=-jKU(\Phi_{L1}+\Phi_{L0})-jK\Phi_{L2}\left(Y-\frac{1}{3}\right) \quad (4)$$

$$\therefore \Phi_M=\frac{j}{K}E_2-\frac{j}{K}\left[-jKU(\Phi_{L1}+\Phi_{L0})-iK\Phi_{L2}\left(Y-\frac{1}{3}\right)\right]$$

or

$$\Phi_M=\frac{j}{K}E_2-U(\Phi_{L1}+\Phi_{L0})-\Phi_{L2}\left(Y-\frac{1}{3}\right)$$

Substituting this value of Φ_M in the equation of Φ_C above gives

$$\Phi_C=\frac{j}{K}E_2-U(\Phi_{L1}+\Phi_{L0})-\Phi_{L2}\left(Y-\frac{1}{3}\right)+Y\Phi_{L2}+U(\Phi_{L1}+\Phi_{L0})$$

$$\therefore \Phi_C=\frac{j}{K}E_2+\frac{1}{3}\Phi_{L2} \quad (5)$$

It is, therefore, evident that it makes no difference in the value of Φ_C what assumptions are made regarding the return of the leakage flux since neither Y nor U occurs in the expression for Φ_C.

Referring to the last equation since Φ_{L2} has already been expressed in terms of I_2 (equation 1), it is now necessary to determine E_2 in terms of I_2. This is readily accomplished by adding the internal secondary IR drop to the secondary terminal voltage since E_2 by definition is the net voltage induced by all fluxes including leakage.

$$\therefore E_2=V_2+I_2R_2$$

but

$$V_2=I_2R_B+jI_2X_B$$
$$\therefore E_2=I_2(R_2+R_B)+jI_2X_B$$

Substituting in equation 5 this value of E_2 and the value of Φ_{L2} given in equation 1 in terms of I_2 gives

$$\Phi_C=I_2\left[\frac{j}{K}(R_B+R_2)\right]+\frac{j}{K}(jI_2X_B)+\frac{1}{3}\left(3.2\,\frac{N_2I_2}{2L_2}A_2\right)$$

or

$$\Phi_C=I_2\left[\frac{j}{K}(R_B+R_2)-\frac{X_B}{K}+.533\,\frac{N_2A_2}{L_2}\right] \quad (6)$$

To determine the fluxes at other points in the core it is necessary to know how much of the leakage enters the core between various points in its length. In general, it can be assumed that all the leakage flux which passes through and between the copper inside the core window enters the core. Of the remainder about 50 per cent will enter the core between sections 1 and 5.

If Φ_{LT} = flux entering the core between sections 1 and 5,

$$\Phi_{LT}=(\Phi_{L1}+\Phi_{L0}+\Phi_{L2})\times\left[\frac{h}{MLT_0}+\frac{1}{2}\left(1-\frac{h}{MLT_0}\right)\right]$$

Where h = height of core in the case of a "core" type core or twice the height in the case of a shell-type core and MLT_0 = mean length in the direction of the windings around the space between the windings

$$\therefore \Phi_{LT}=\left(\frac{\Phi_{L1}+\Phi_{L0}+\Phi_{L2}}{2}\right)\left(1+\frac{h}{MLT_0}\right)$$

Of Φ_{LT} a certain fraction, K_1 will enter the core between sections 1 and 2, another fraction, K_2, will enter between 1 and 3, and another fraction, K_3, between 1 and 4. The values of K_1, K_2, K_3, will be usually in the neighborhood of 0.57, 0.87, and 0.93 respectively. With these values of leakage flux entering the core the values of flux at the sections 2, 3, 4, and 5 will be given as follows, the subscripts after the Φ denoting the section:

$$\Phi_2=\Phi_C-K_1\Phi_{LT}=I_2\left[\frac{j}{K}(R_B+R_2)-\frac{X_B}{K}+\frac{0.533N_2A_2}{L_2}\right]-K_1\Phi_{LT} \quad (7)$$

$$\Phi_3=\Phi_C-K_2\Phi_{LT}=I_2\left[\frac{j}{K}(R_B+R_2)-\frac{X_B}{K}+\frac{0.533N_2A_2}{L_2}\right]-K_2\Phi_{LT} \quad (8)$$

$$\Phi_4=\Phi_C-K_3\Phi_{LT}=I_2\left[\frac{j}{K}(R_B+R_2)-\frac{X_B}{K}+\frac{0.533N_2A_2}{L_2}\right]-K_3\Phi_{LT} \quad (9)$$

$$\Phi_5=\Phi_C-\Phi_{LT}=I_2\left[\frac{j}{K}(R_B+R_2)-\frac{X_B}{K}+\frac{0.533N_2A_2}{L_2}\right]-\Phi_{LT} \quad (10)$$

The flux densities, β_C, β_2, β_3, β_4, and β_5 corresponding to the fluxes Φ_C, Φ_2, Φ_3, Φ_4, and Φ_5 are, of course, the absolute values of these fluxes divided by the cross-sectional areas of the core at the respective points, and the sines of the angles θ_C, θ_2, θ_3, θ_4, and θ_5 between β_C, β_2, β_3, β_4, and β_5 respectively and the secondary current reversed are the imaginary components of the fluxes divided by the absolute values (see figure 2). It should be noted that θ_C may be greater than 90 degrees.

If α_C, α_2, α_3, α_4, and α_5 (figure 3) are the angles between the flux densities and their respective unit values of exciting ampere turns* i_C, i_2, i_3, i_4, and i_5, as determined from magnetization data on the iron, then by averaging the values for each section of length the components of exciting ampere turns in phase with the secondary current reversed will be:

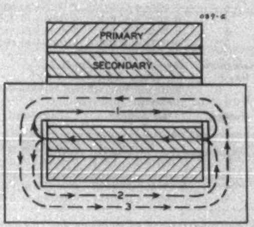

Figure 6. Paths of leakage flux which does pass through secondary copper

$$\frac{L_{12}}{2}[i_C\cos(\theta_C-\alpha_C)+i_2\cos(\theta_2-\alpha_2)]$$
for section 1–2

$$\frac{L_{23}}{2}[i_2\cos(\theta_2-\alpha_2)+i_3\cos(\theta_3-\alpha_3)]$$
for section 2–3

$$\frac{L_{34}}{2}[i_3\cos(\theta_3-\alpha_3)+i_4\cos(\theta_4-\alpha_4)]$$
for section 3–4

$$\frac{L_{45}}{2}[i_4\cos(\theta_4-\alpha_4)+i_5\cos(\theta_5-\alpha_5)]$$
for section 4–5

Where the L's represent the lengths between the sections denoted by the subscripts. Since there are two of each of the above sections in the whole core the total component of exciting ampere turns in phase with the secondary current reversed will be given by

$$\Sigma i\cos(\theta-\alpha)=L_{12}i_C\cos(\theta_C-\alpha_C)+(L_{12}+L_{23})i_2\cos(\theta_2-\alpha_2)+(L_{23}+L_{34})i_3\cos(\theta_3-\alpha_3)+(L_{34}+L_{45})i_4\cos(\theta_4-\alpha_4)+L_{45}i_5\cos(\theta_5-\alpha_5)$$

Similarly the component of exciting am-

1		0.0065 − j0.0076
2	0.0064 + j0.0315	0.0065 + j0.035
3	0.0063 + j0.057	0.0065 + j0.058
4	0.0066 + j0.061	0.0065 + j0.062
5	0.0075 + j0.064	0.0065 + j0.067

Transformer No. 3 Secondary short-circuited
Secondary amperes = 4.85
Volts per turn referred to secondary current

Section	Measured*	Calculated
1		0.0058 − j0.0033
2	0.00616 + j0.0064	0.0058 + j0.0064
3	0.00630 + j0.0113	0.0058 + j0.0115
4	0.00640 + j0.0125	0.0058 + j0.0127
5	0.00656 + j0.0144	0.0058 + j0.0138

*Values are average of values obtained on two transformers. Samples differed by almost 20 per cent.

Transformer number 1—General Electric type *KF*-85.

Transformer number 2—General Electric type *KF*-58.

Transformer number 3—General Electric type *WF*-12.

pere turns 90 degrees out of phase with the secondary current is given by

$$\Sigma i \sin(\theta-\alpha)=L_{12}i_C \sin(\theta_C-\alpha_C)+(L_{12}+L_{23})i_2 \sin(\theta_2-\alpha_2)+(L_{23}+L_{34})i_3 \sin(\theta_3-\alpha_3)+(L_{34}+L_{45})i_4 \sin(\theta_4-\alpha_4)+L_{45}i_5 \sin(\theta_5-\alpha_5)$$

Since these components of exciting ampere turns must be added to the secondary ampere turns reversed to obtain the primary ampere turns the latter are given by

$$N_1I_1=-N_2I_2-\Sigma i\cos(\theta-\alpha)+j\Sigma i\sin(\theta-\alpha)$$

as shown in figure 4.

Therefore, ratio correction factor is†

$$RCF=\sqrt{\left[1+\frac{\Sigma i\cos(\theta-\alpha)}{N_2I_2}\right]^2+\left[\frac{\Sigma i\sin(\theta-\alpha)}{N_2I_2}\right]^2}$$

and the phase angle is

$$\beta=\sin^{-1}\frac{\Sigma i\sin(\theta-\alpha)}{N_1I_1}$$

If the common method of compensating by changing secondary turns is employed this percentage, of course, must be subtracted from the value computed above. Other special methods of compensation require special calculations of their own to compute the final accuracy, although it is usually necessary to compute the uncompensated accuracy first in any event.

Discussion and Review

An inspection of the results of the analysis reveals some interesting facts. In the first place equations 6 to 10 inclusive show that the component of flux 90 degrees out of phase with the secondary current is the same in all sections of the core.

Actually this is not strictly true as in transformers having large primary conductors the eddy currents tend to make the leakage flux lag the primary current so that a component of the leakage shows up 90 degrees out of phase with the primary and secondary turns. The magnitude of this component of the leakage flux however, is almost always quite small compared to the average value of total flux in the core as shown by table I.

Equations 6 and 10 show that if the external burden and internal resistance are small Φ_C and Φ_s may be almost 180 degrees apart. This may seem unreasonable but actual flux measurements on the core show it to be true.

It will be noticed that no mention has been made of secondary reactance. The term was not used because it necessitates defining a rather elusive quantity which is not of any particular value in solving the problem. The term is elusive and confusing because reactance, being volts divided by amperes, depends on the voltage induced by the secondary leakage flux which, as has been seen, depends on the direction of return of this leakage. Moreover, the secondary leakage flux, Φ_{Ls} must return outside the secondary coil if the in-phase component of Φ_C is negative, as is generally the case (see equation 6), because if one is to adhere strictly to physical realities there cannot be flux flowing in opposite directions in the same section of the core at the same instant. If Φ_{Ls} does all return outside the secondary, the voltage generated is positive and hence the reactance must be negative. If, on the other hand, the in-phase component of Φ_C is $+{}^1/_3\,\Phi_{Ls}$, the maximum value without leading power factor burden, then ${}^1/_3\,\Phi_{Ls}$ returns inside the secondary. Referring to equation 4 this means $Y={}^1/_3$ and hence the voltage induced by the secondary leakage flux equals zero. Therefore, if reactance is to be defined in the conventional manner and the flux paths are to be taken exactly as they are, the only conclusion is that the secondary reactance is a variable depending on the external burden and varying between zero and $-K\Phi_{Ls}/3I_s$. It is consequently evident that the use of the term "secondary reactance" is of no advantage in this analysis, as a rigorous definition of such a term makes it necessary to solve most of the problem to determine the reactance.

Tables I, II, and III give comparisons of calculated and measured results. Transformers numbers 1 and 2 were different in size but of similar design while the proportions of transformer number 3 were considerably different from the first two. An inspection of the tabulated values shows that there is still some room for improvement in the accuracy of the calculations which further study and added refinements might produce. On the other hand, the discrepancies between the calculated and the measured values of flux are no greater than the errors frequently incurred in computing the physical dimensions of the coils and the space between them. In fact, to go even further, tests show that in some cases the variation between individual samples of the same design is greater than the error of the calculations. Moreover, both tests and simple computation show that what appears to be a small degree of dissymmetry in the coils will frequently cause a large difference between the values of flux in the opposite ends of the core. From a practical point of view, therefore, further refinement in the method of calculating the flux will not produce the improvement in over-all results which would be expected at first glance.

Moreover, any such refinements in the calculations would be largely a matter of field theory in determining the exact conformation of the leakage flux outside the core rather than any alteration of the principle involved and in the writer's

Table II

Transformer Number 1—Leakage Fluxes, Secondary Short-Circuited, Secondary Amperes = 5.0

	Crest Values of Flux	
	Measured	Calculated
Φ_{Ls}	9,450	8,750
$\Phi_{Le}+\Phi_{Li}$	25,650	28,000
$\Phi_{Li}+\Phi_{Le}+\Phi_{Ls}$	35,100	36,800
Negative flux at center of secondary	3,490	2,920
Flux in item above divided by Φ_{Ls}	0.37	0.33
Φ_{LT}	20,270	21,500

opinion the chief value in the foregoing analysis is the establishment of the general theorem by which the flux densities in the core can be determined from a given conformation of leakage flux, ampere turns, secondary burden, etc. A concrete illustration of this statement is afforded by the bar or through-type transformer having a single primary turn. In this type the magnetic field is altogether different from the wound type, and a totally different method of evaluating the leakage flux must be used, but having established the values of leakage flux entering the core the method of determining the flux densities in the core is exactly the same as with the wound type. In passing it might be mentioned that in the case of high-current bar or through-type transformers, particularly those with only two secondary coils, the leakage flux is generally of much more importance than in other designs.

A detailed discussion of a precise definition of accuracy including the effects of wave-form errors is beyond the scope of this paper, but since the exciting current is responsible for the added complications of harmonics the subject of wave form should not be passed over without mentioning the importance of the method of making exciting-current tests. At high flux densities in magnetic cores harmonics become a large per cent of the effective values of voltage or current or both depending on the test setup, and results may vary over a wide range depending on the wave form of voltage applied and the methods of measurement. On the basis of both experience and theoretical considerations, in the writer's opinion, the most satisfactory method of making exciting-current tests for current-transformer accuracy calculations is to apply a sine-wave voltage to a coil of low resistance wound on the core, and measure both the current and the voltage with an instrument such as a vibration galvanometer or separately excited dynamometer instrument which will give the fundamental components of the voltage and current waves. For tests at very high density the actual transformer coils and core should be used, the exciting current being applied to the primary coil and the voltage measured on the secondary.

While the method of calculation here presented is subject to the limitations implied in the assumptions and discussed previously, it can be used with reasonably good results for the calculation of overcurrent accuracy up to a current where the maximum magnetizing force in the core is about 300 ampere turns per inch. For many cases this will be high enough. Curves, figures 7 and 8, show results that may be expected up to limit specified. On some transformer designs which by virtue of their geometry have no leakage entering the core, the flux density in the magnetic circuit is uniform throughout its length. In such cases, the overcurrent calculations can be carried out successfully above the limit specified above.

With regard to the practical value of the method of calculation here presented, the method is quite useful in designing transformers to meet special requirements or specifications. It is also valuable in comparing the worth of proposed designs, and its value in this respect is enhanced by the fact that to test such proposed designs it is necessary to make several samples on account of the uncertainty with most core materials in obtaining a representative core in any particular sample. Another value in the method of calculating the accuracy is to be able to compare the relative advantages of different core materials in a given design, where again, if actual tests are made a number of cores will usually have to be tried before a representative sample is obtained. However, in this case where

Table III. Accuracy (Without Wilson Compensation)

Transformer Number	Burden (Ohms)	Secondary Amperes	Measured Values: Ratio Correction Factor	Measured Values: Phase Angle (Minutes)	Calculated Values: Ratio Correction Factor	Calculated Values: Phase Angle (Minutes)
1	$R=0.24$, $X=0$	0.5	0.9994	5	1.0002	4

transformers are probably available it is almost as quick and more accurate to make measurements of flux in the core, thereby eliminating that much computation. If data are then available on the materials to be considered, the accuracy can be computed from these data and the flux measurements.

Moreover, since considerable equipment and expense are involved in making overcurrent accuracy tests, it is, of course, quite valuable to be able to calculate the performance at high currents particularly in designing apparatus for special requirements when there is usually not time to build and test samples.

Appendix

Voltage Induced by Leakage Flux in Secondary; Proof of Equation 4

In verifying equation 4, first consider the leakage $(\Phi_{L0}+\Phi_{L1})$ figure 5. Since all this flux in traversing the space occupied by the coils passes outside the secondary copper, all that returns along the paths represented by the solid lines links all the secondary turns and all that returns along the dotted paths links no secondary turns. Hence, the voltage induced by the amount that returns outside the secondary will be zero and that which returns inside the secondary coil will generate a voltage equal to $2\pi f N_2 \cdot 10^{-8} U \cdot (\Phi_{L0}+\Phi_{L1})$ since U is by hypothesis the fraction returning inside the secondary. Also, since $U(\Phi_{L0}+\Phi_{L1})$ is in phase with the secondary magnetomotive force the voltage generated is $-jKU(\Phi_{L0}+\Phi_{L1})$ referred to the secondary current.

To determine the voltage generated by Φ_{L2} consider any one particular line of flux as shown in figure 6. Let the fraction of the secondary turns between this line of flux and the inside of the secondary coil equal S. If the line of flux returns along the path number 1, the voltage generated is $-jKS$. If, on the other hand, the line of flux returns along path number 2, the voltage is $+jK(1-S)$. The algebraic difference, $jK(1-S)-(-jKS)$ is readily seen to be jK. Hence, the difference in generated voltage obtained by changing the return of the flux line from path number 1 to path number 2 is jK and is the same as the voltage generated by a line following path number 3. But the flux line considered is any line passing through the secondary copper, and, therefore, the result must be true for all such lines. Consequently, the voltage difference due to changing the paths of N such lines from inside to outside is jKN. Therefore, if the voltage generated by assuming all Φ_{L2} returns along path number 1 is E_0, the voltage E_A, generated when $(1-Y)\Phi_{L2}$ lines return along path number 2 is $E_A=E_0+jK(1-Y)\Phi_{L2}$ where Y is, of course, the fraction of Φ_{L2} returning inside the secondary as assumed in equation 4.

It can be shown* that if d_4 = the mean radius of the inside of the secondary coil (that is, $^1/_{2\pi}$ times the length at the inside turn) and d_2 = the thickness of winding in inches, the voltage E_0 is given by the equation

$$E_0=-j2\pi f\left\{\frac{0.8\pi^2N_2^2I^2}{L_2}\left[\frac{d_4d_2}{3}+\frac{d_2^2}{4}\right]\right\}\times (2.54)10^{-8}$$

the 2.54 being the factor to change the formula from centimeters to inches.

$$\therefore E_0=-jK\left(\frac{6.4N_2I_2}{L_2}\right)\left[\frac{d_4d_2}{3}+\frac{d_2^2}{4}\right](\pi)$$

and

$$\Phi_{L2}=\frac{6.4N_2I_2}{L_2}\left[\frac{d_4d_2}{2}+\frac{d_2^2}{3}\right](\pi) \qquad (11)$$

$$\therefore \frac{E_0}{\Phi_{L2}}=-jK\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right)$$

or

$$E_0=-jK\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right)\Phi_{L2}$$

$$E_A=-jK\Phi_{L2}\left[\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right)+Y-1\right]$$

since

$$E_A=E_0+jK(1-Y)\Phi_{L2}$$

or

$$E_A=-jK\Phi_{L2}\left[Y-\left\{1-\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right)\right\}\right]$$

if

$$\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right) \qquad (12)$$

is set equal to q and m equal to $(1-q)$, then

$$E_A=-jK\Phi_{L2}[Y-m] \qquad (13)$$

It is evident that q will be between $^2/_3$ and $^3/_4$. As a matter of fact, it will be generally very nearly $^2/_3$ making m very nearly $^1/_3$. It can, moreover, be shown that the value of $m\Phi_{L2}$ is exactly the same if Φ_{L2} is calculated as shown in equation 1 and m is taken equal to $^1/_3$ as it is if m and Φ_{L2} are computed as shown in formulas 11 and 12.

Using the latter combination it is seen that

$$m\Phi_{L2}=(1-q)\Phi_{L2}=\left[1-\left(\frac{\dfrac{d_4}{3}+\dfrac{d_2}{4}}{\dfrac{d_4}{2}+\dfrac{d_2}{3}}\right)\right]\times \left[6.4\pi\frac{N_2I_2}{L_2}d_2\left(\frac{d_4}{2}+\frac{d_2}{3}\right)\right]$$

$$m\Phi_{L2}=6.4\pi\frac{N_2I_2}{L_2}d_2\left(\frac{d_4}{2}+\frac{d_2}{3}-\frac{d_4}{3}-\frac{d_2}{4}\right)$$

$$m\Phi_{L2}=6.4\pi\frac{N_2I_2}{L_2}d_2\left(\frac{d_4}{6}+\frac{d_2}{12}\right)$$

whereas if Φ_{L2} is computed as in equation 1

$$\Phi_{L2}=\frac{3.2N_2I_2}{2L_2}\left[2\pi\left(d_4+\frac{d_2}{2}\right)d_2\right]$$

$$\Phi_{L2}=\frac{3.2N_2I_2}{L_2}\pi d_2\left(d_4+\frac{d_2}{2}\right)$$

$$=\frac{6.4\pi N_2I_2}{L_2}d_2\left(\frac{d_4}{2}+\frac{d_2}{4}\right)$$

$$\therefore \frac{1}{3}\Phi_{L2}=6.4\pi\frac{N_2I_2}{L_2}d_2\left(\frac{d_4}{6}+\frac{d_2}{12}\right)$$

which is exactly the same as the value of $m\Phi_{L2}$ above.

While the method of calculating Φ_{L2} as given in equation 1 gives a slightly lower value than that of equation 11 the value of Φ_{L1} is higher so that the total leakage $(\Phi_{L2}+\Phi_{L0}+\Phi_{L1})$ is practically the same either way; and equations 1, 2, and 3 are somewhat simpler to use.

Therefore, using the latter formulas for the leakage fluxes and taking $m={}^1/_3$ it is evident from quotation 13 that

$$E_A=-jK\Phi_{L2}(Y-{}^1/_3)$$

Now the voltage generated by the leakage fluxes, E_{L2} has two parts, one, that generated by Φ_{L0} and Φ_{L1} shown in the first part of the appendix to be $-jK(\Phi_{L0}+\Phi_{L1})U$ and second, the part generated by Φ_{L2} which is E_A

$$\therefore E_{L2}=-jKU(\Phi_{L0}+\Phi_{L1})-jK\Phi_{L2}(Y-{}^1/_3)$$

This relation is readily seen to be equation 4 given previously.

Reference Values for Temperature, Pressure, and Humidity

P. L. BELLASCHI
FELLOW AIEE

P. H. McAULEY
ASSOCIATE AIEE

IN most engineering measurements the readings obtained at a given time depend upon a number of conditions, such as temperature and barometric pressure, existing at the time of the test. In some cases the effects are very small, compared to the accuracy desired in the result, and can be neglected. In other cases prevailing conditions have a decided effect on the numerical values of the test results. For instance, in a determination of the boiling point of water, it is very necessary to consider the barometric pressure. In measuring the flashover voltage of an insulator, the temperature, pressure, and humidity each has a measurable effect on the observed value. Therefore, it has become necessary to select standard conditions to which certain measurements may be referred. This permits measurements made in different laboratories or at different times in the same laboratory to be compared directly. Certain values have been chosen, such as 760 millimeters barometric pressure, to which measurements for any physical or electrical quantity usually are referred, regardless of where in the world a particular measurement is made. This is a very convenient practice and greatly simplifies comparisons and use of engineering data.

It is therefore proposed to consider reference values for the temperature, the atmospheric pressure, and the humidity of the air. Because of their influence on measurements and on the rating of apparatus, the effects of these conditions have been analyzed. Reference values have been selected and correction factors for nonstandard conditions determined by interested standardizing groups. Certain values have been chosen as reference values because of average conditions prevailing at the time original tests were made or because of ease in maintaining a certain condition. A review of current practices indicates that 20 degrees centigrade is a favored reference value for physical and chemical quantities in both United States and international use. On the other hand 25 degrees centigrade is deeply rooted in American electrical practice. The agreement on a barometric pressure of 760 millimeters is universal. With respect to humidity, there is not much consistency in the reference values used or in the units in which they are specified. Humidity is important in fewer cases and its effects have been appreciated and evaluated more recently.

At times there is little advantage in the use of one reference value over another and, lacking organized co-ordination, slightly different values have been introduced in various standards. Although it may be impractical to remedy this undesirable condition in all cases, it is hoped that the information collected here will help to avoid further complication by minimizing the reference values adopted in future standards.

From an engineering point of view there are two types of reference values; in one case the value is of the nature of an average to which values obtained throughout a range of conditions may be referred or corrected. In the second case the problem is one of maximum values rather than average. This condition occurs notably in connection with the thermal limits and therefore the rating of electrical machinery. For rating purposes, the engineer is interested principally in ambient temperatures exceeding certain values and the time during which they prevail. The ambient-tem-

perature considerations which determine apparatus rating are covered elsewhere,[5,13] notably in AIEE Standard No. 1.

In choosing and correcting to standard reference conditions, simplicity of the method is very desirable. Therefore, the reference value should be selected to represent approximately average actual conditions and to make the correction process as simple as possible. In this connection, the background and development of present standard reference conditions are discussed. Furthermore, the importance of dependable correction factors to convert performance data to the reference conditions is considered.

Temperature

(A). Reference Values

Certain specific values in connection with temperature are easily determined from well-known physical characteristics. The freezing and boiling points of water are examples. Another value is the point of maximum density of water at four degrees centigrade. In the beginning, the temperatures, at which measured quantities are given, depended upon the ease of obtaining certain temperature conditions. As progress was made the desirability of using a single or fewer reference temperatures became apparent. Table I shows some of the reference temperatures for physical and chemical quantities in United States and international use. These values were taken more or less at random from a number of standard handbooks and engineering tables. It is apparent from this table that 0 and 20 degrees centigrade are the reference temperatures now in most common use for such quantities.

Another common reference value which has been adopted, particularly for electrical-engineering use in this country, is 25 degrees centigrade. This value was established as the reference for testing apparatus. In the report of the standards committee and in companion papers presented at the 1913 AIEE midwinter symposium on standardization and apparatus rating,[1] the following parts sum up essentially the basis and reasons recognized at that time for selecting the 25-degree-centigrade value:

> "The reference temperature in the guarantees should, therefore, be such as can easily be secured; that is, it should be the average temperature of the places at which the apparatus may be operated. This is from 20 degrees centigrade to 25 degrees centigrade and, as it is easier to raise than to lower the room temperature, the upper figure is advisable as a reference value. This reference temperature, therefore, should be chosen as 25 degrees centigrade, which is in accordance with the previous AIEE standard."
>
> "It is, therefore, recommended . . . that all measurements and tests of electrical apparatus be based on a room temperature of 25 degrees centigrade."

At this same time, Chubb and Fortescue presented calibration data for the 25-, 37.5-, and 50-centimeter sphere gaps.[2] Although temperature and barometric pressure are not mentioned in their article, it is apparent from the discussions that the effect of these conditions was appreciated. The correction formula in use today for temperature and pressure was given by Peek in his discussion. The foregoing explains the use of 25 degrees centigrade in sphere-gap calibration tables in AIEE standards.[4] The use of this temperature has of course grown and for the past ten years, all high-voltage measurements have been referred to this temperature.

The present status of reference values in the electrical field is summed up in table III. In general, 25 degrees centigrade is the reference temperature specified for tests and test data on electrical apparatus in AIEE and ASA standards. On the other hand, AIEE standard on conductors refers to the 20-degree-centigrade temperature. International Electrotechnical Commission Standards[3] on high-voltage practice, insulators, and conductors are based on 20 degrees centigrade.

The American Society for Testing Materials has standardized a wide variety of electrical-insulating material tests for many of which temperature and humidity are important. Table II gives the reference values and specified testing ranges for a number of ASTM standards. This group has recognized the situation for some time and are aiming at a reference value of 25 degrees centigrade where possible.

(B). Temperature Conditions

For proper selection of reference values, the conditions of location of test as well as location of use are of interest. Therefore it should be useful, at this time, to consider the merits of different reference temperatures in the light of actual conditions recorded over a period of years at typical industrial establishments and of the values reported in the climatic summary of the United States Weather Bureau.[6]

(*a*). *Outdoor Use and Laboratories.* Figure 1*A* shows temperature readings over a period of several years at the Sharon, Pa., high-voltage laboratory of the Westinghouse Electric and Manufacturing Company, recorded in the course of commercial and

---

[5] For all numbered references, see list at end of paper.

development testing of station apparatus. At this laboratory, tests on apparatus were made outdoors and the values shown, therefore, represent outdoor, daytime temperatures for Sharon. The range in temperature is from −9 degrees centigrade to 36 degrees centigrade, a total spread of 45 degrees centigrade. The annual average is about 15 degrees centigrade. The April–September average is about 24 degrees centigrade and during the winter months close to 0 degrees centigrade.

A detailed survey of these data plotted in figure 1*A* reveals that temperature variations during the day may affect the air density three to four per cent and even more from one day to the next. These variations are clearly apparent from figure 3, in which the daily maximum and minimum temperatures for Sharon covering the 24 hours during 1936 are given. Daily maximum variations frequently are 10 degrees centigrade, occasionally 15 degrees centigrade, and even more during marked changes in the atmospheric conditions. From similar charts, the annual average temperature during 1936–38 is 9.6 degrees centigrade, a value substantially lower than the 15 degrees centigrade annual average for figure 1*A*, since the former covers the full 24 hours of the day and thus includes the lower temperatures of the night. The chart for 1936 (figure 3) is of further particular interest as it shows a maximum peak temperature close to 41 degrees centigrade (July) and a minimum peak of −26 degrees centigrade (January), both of which, however, were sustained for a relatively short time. The spread between the more sustained maximum and minimum peak values is 60 degrees centigrade, to which there corresponds then a total air-density change of 22 per cent.

The climatic summary of the United States Weather Bureau gives data on temperatures that have been recorded at numerous stations located throughout the entire country. Average temperatures for 24 typical locations are listed in table IV. Locations 1 to 15 are distributed in the hot-summer and cold-winter region. This is the northeastern region between 38 degrees north and 45 degrees north latitude, which extends from approximately 105 degrees west longitude to the Atlantic Seaboard. In this region are located some three-quarters of the population and the major activities of the country. Curve *A* of figure 2 gives the temperature curve for this region as determined from these representative locations. Curve *B* is for two locations at approximately 34 degrees north latitude and curve *C* for two other locations on the 30 degrees north latitude. These curves clearly bring out the change in temperature cycle from north to south, that is, from the hot-summer and cold-winter region into the hot-summer and mild-winter region. Curve *D* is for the extreme southern fringe of the country. Due to the moderating meteorological influences on the Pacific Coast, the temperature for locations 21 to 24 (table IV) are more uniform than at corresponding latitudes in the east. For the northeastern region, the annual average (curve *A* of figure 2) is 11 degrees centigrade; the May-to-August average is 20.8 degrees centigrade. For the southeastern region, the annual average (curves *B* and *C*) is 18.7 degrees centigrade and the May-to-August average, 25.9 degrees centigrade. The annual average for the entire United States over a period of 50 years is 12.7 degrees centigrade.

In addition, the climatic summary gives the average maximum and minimum temperatures. These two limits vary from the average an amount depending on the location. For Pittsburgh which is an "average" location in the northeastern region, the spread of the average maximum and minimum temperatures from the annual average curve is about five degrees centigrade for practically the entire year. Much larger daily variations can occur as it is clearly shown in figure 3. The average temperatures for Sharon, Trafford, and East Pittsburgh come within one to two degrees centigrade of the Pittsburgh values (location 8 in table IV). It is apparent then that the temperature data recorded indoors and outdoors in testing apparatus, which are presented and discussed in this paper, are quite typical of conditions[12] that are expected elsewhere in the northeastern section of the country.

(*b*). *Typical of Large Factory Buildings, Machine Test Floors, and Large Laboratories.* Figure 1*C* shows temperature conditions for a period of years at the Trafford high-voltage laboratory. Here the testing is done indoors although the building is not well insulated and there are many places around doors which are not tight. It is seen that the average temperature throughout the year is around 23 degrees centigrade. This is very close to the standard temperature to which corrections are made. The variations in temperature measurements in this heated building are due to the high temperature gradient from floor to ceiling and represent conditions that generally are encountered in high-voltage laboratories. The distance from the floor to the roof is 65 feet and at times the gradient may reach 0.5 degree centigrade per foot. The temperature values shown in the figure were taken for all kinds of tests, but usually at the level at the apparatus being tested. For a rod gap on the floor, the temperature was measured 3 to 4 feet

Table II. Reference Values and Testing Temperatures, in the Room-Temperature Range, Specified in October 1939 ASTM Standards on Electrical Insulating Materials

Material	Test or Treatment	Temperature or Temperature Range (Deg C)	Relative Humidity (Per Cent)
Sheet and plate	Physical	25 ±8	
	Conditioning	25	40
Laminated tubes	Physical	25 ±8	
Laminated rods	Physical	25 ±8	
Varnished cloth	Elongation	20 to 30	
Varnishes	Density	25 ±1	
	Viscosity	25 ±0.2	
	Time of drying	25	
	Conditioning	25 water	
Varnished cloth	Conditioning	20 to 30	60 to 65
	Power factor	25 to 30	
Flexible varnished tubing	Conditioning	20 to 30	50 to 55
	Aging	20 approx.	
Shellac	Iodine number	21.5 to 22.5	
Shellac varnish	General	21 to 32	
	Iodine number and drying time	20 to 30	
	Special	20	65
	Specific gravity	20	
Molded materials	Tensile strength	20	
	Dielectric	25	
	Water absorption	25 ±2	
Phenolic laminated sheet	Power factor	20 to 30	
Laminated tubes	Water absorption	25 ±2	
Laminated round rods	Water absorption	25 ±2	
Sheet and plate	Tensile strength	20	
	Rate of absorption	25 ±2	
	Total absorption	20 to 30	
	Bonding strength	20 approx.	
	Hardness	25 ±2	
Insulating oils	Dielectric	20 to 30	
Electrical porcelain	Tensile strength	20 approx.	
Filling and treating compounds	Power factor	20 to 25	
Untreated paper	Conditioning	20 to 30	65
Friction tape	Adhesion	20 to 22.2	less than 80
Rubber tape	Physical	20 to 28	
Rubber gloves	Electrical	15 to 32	
Asbestos yarns	Conditioning	21	65

above the floor and for a suspension-insulator string, the temperature measurement might be made as high as 30 feet above the floor. The average temperatures experienced indoors at Sharon are shown in figure 1*B*. These temperatures were recorded at one of the test floors where apparatus is subjected to the usual standard commercial tests as well as to other tests that may be required. The form of this average curve is practically similar to that of figure 1*C*.

(*c*). *Typical of Living Quarters Such as Homes, Offices, and Laboratories in Smaller Rooms.* In a well-heated building, consisting of smaller quarters, during the winter months, the temperature is 24 ±1 degrees centigrade. This conclusion has been reached from the temperature measurements over a period of time in the engineering laboratory building at East Pittsburgh.

From the foregoing, therefore, the problem of reference temperature and correction factors is twofold. In the first place, the desirability of keeping corrections small should be kept in mind chiefly because of inaccuracies and variations in the original correction-factor data. The undesirable effect of discrepancies due to very large correction factors can be somewhat minimized by using reference values representing average conditions. Thus, for outdoor testing as in case (*a*), in correcting data to a standard temperature of 25 degrees centigrade the corrections are, in most cases, larger than if a lower temperature were used as a reference value. The 25-degree-centigrade reference value has merit for case (*c*) and also for case (*b*), though it is apparent that there is not much to choose between 25 degrees centigrade and 20 degrees centigrade in these two cases. However, as a general rule, it is desirable to have the reference temperature higher rather than lower than the average, for it is easier to heat than to refrigerate to obtain standard conditions for testing. The second part of the problem pertains to dependable correction factors which are desirable in view of the inherent variations in atmospheric conditions.

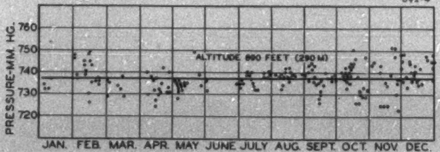

Figure 4. The barometric pressures for tests at Sharon, 1936–38

Barometric Pressure (Altitude)

The barometric pressure of 29.92 inches (760 millimeters) of mercury has been adopted universally as a standard reference value. This represents average conditions at sea level. The pressure of the atmosphere affects the thermal limits and the voltage rating of apparatus. Much apparatus is tested and used at elevations above sea level and consequently these effects cannot be ignored.

For a given location, however, the variations encountered in barometric pressure throughout the year are relatively small. Figure 4 shows readings at the Sharon laboratory during 1936–38. Each reading was taken at the time of a voltage flashover test. A ±1.5 per-cent band from the average includes practically all variations and a detailed examination of the records shows that diurnal variations seldom exceed 0.5 per cent. In a few instances only did the barometer vary from one day to the next as much as 2 per cent. To the meteorologist, these variations are an important measure of the trend in the weather or of prevailing conditions, but for the engineering purpose of this survey, the data hardly permit other than an average curve drawn through 735 millimeters mercury. This average value of mercury column corresponds quite well with the altitude of the Sharon laboratory which is 890 feet (290 meters). The effect of altitude on barometric pressure[7] is shown in figure 5.

The AIEE TRANSACTIONS for 1913 indicate that the standards in use at the time prescribed a correction of one per cent of the observed rise in the temperature of apparatus for each 10-millimeter deviation from the standard pressure of 760 millimeters. The present standards state that specified ratings hold for elevations up to 1,000 meters. This is a gratifying example of the simplification of practice in using a reference value, which is so desirable. It is noted in passing that AIEE Standard No. 11 for Railway Motors states: "Machines rated in accordance with these standards may be tested at any altitude not exceeding 1,200 meters and no correction shall be applied to the observed temperature rise". AIEE Standard No. 16 for Railway Control Apparatus gives the usual figure of

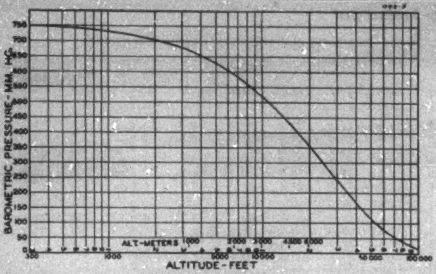

Figure 5. The effect of altitude on barometric pressure

1,000 meters. AIEE Standards for Transformers in addition to the 1,000-meter range give a correction for temperature rise tests made at altitudes greater than 1,000 meters.

At 1,000 meters the normal barometric pressure is 675 millimeters. Based on the old AIEE rule, an observed temperature rise at this altitude would be reduced eight per cent by the correction. As indicated above, present practice is to ignore altitude corrections up to 1,000 meters and to classify equipment for use at higher altitudes as "high-altitude apparatus". This applies to voltage as well as to thermal ratings. This simplification of the problem recognizes the impropriety of permitting a few applications to complicate the majority of ratings and measurements. For voltage flashover measurements, however, it is standard practice to combine barometric and temperature corrections under relative air density.

A recent occurrence is a backward step in progress toward uniformity of engineering practice. The United States Weather Bureau in July 1, 1939, adopted the practice of using the millibar as the unit of pressure. A bar is one dyne per square centimeter and 1,013.3 millibars corresponds to 760 millimeters, the standard atmospheric pressure. Several years ago the millibar was adopted for aerological observations and enjoys international use in this limited field. From an engineering point of view this action is regrettable. Barometric pressure invariably is expressed in terms of the height of a mercury column, both in standards and in laboratory practices. The use of Weather Bureau data will therefore require the use of a conversion factor.

The problem of barometric pressure in engineering measurements is a case where a single standard exists and where agreement on the unit of expression is reasonably consistent. Corrections have been minimized by standardizing on a range where possible. This fortunate situation is partly because the range of pressure variations in practice is small and the effects thereof on measurements and ratings correspondingly small. The growing use of electrical apparatus for aeroplanes eventually may lead to some modifications of present practices concerning ratings.

Humidity

Nearly 30 years ago the effects of humidity of the air on temperature rises of machinery were investigated and found to be negligible. It was also found that sphere-gap spark-over values were not influenced by humidity. Changes in

Table III. Reference Values in Apparatus Standards

		Reference Values**

* Average for the various locations in from 40 to 100 years.

flashover values of insulators and point gaps with humidity were observed, but it was less than 10 years ago that more complete quantitative tests[8] were started. AIEE Standards No. 41 for insulators gave a formula for determining the humidity from the wet- and dry-bulb temperature readings in terms of the vapor pressure in inches of mercury and specified 0.6085 inch as the standard humidity. It was stated that flashover voltage shall be determined at or corrected to this standard humidity, but no correction factors were given and the control of humidity for much high-voltage testing was impractical. The standard humidity value was arrived at by choosing 65 per cent relative humidity at 25 degrees centigrade and 760 millimeters pressure as the standard. This represents average conditions in the summer months when many insulation troubles appear due to lowered leakage resistances and to the lightning season.

The annual humidity variations at the Sharon and Trafford laboratories as measured in the course of high-voltage testing are shown in figures 6 and 7 and may be regarded as typical of the more populated sections of the country. Diurnal variations in the absolute humidity of 0.10 inch mercury are common, but seldom exceed 0.20. From one day to the next, the humidity may vary from 0.20 to 0.30 inch mercury. The total spread for the year may reach 0.80 inch mercury, to which amount there corresponds a humidity correction factor of 25 per cent for some of the station and line apparatus. The annual average for the recorded data in the figures is close to 0.40 inch mercury. In the summer months, the average is above 0.60 inch mercury. It is at once seen that from a laboratory viewpoint the 0.6085 inch standard is too high. About 80 per cent of the testing is carried on at substandard conditions. This means a higher percentage correction factor and test results are correspondingly more at the mercy of the accuracy of the correction factors. These, of course, were based on a limited amount of data. However, the difficulties of changing the standard on which so much work has been based in determining insulation values and in setting insulation levels have made acceptance of the above undesirable feature much more attractive than the confusion of changing.

The laboratory subcommittee[9,10] of the EEI–NEMA Joint Committee on Coordination of Insulation have been working on the problem of the influence of humidity in connection with insulation problems for many years. Similarly, the International Electrotechnical Commission has carried on work of this nature abroad. The IEC has adopted a standard humidity of 11 grams per cubic meter, which corresponds to 0.45 inch vapor pressure. This is much closer to average testing conditions throughout the year. It would be convenient to have the United States and International standard agree to facilitate comparing data. This is a matter for the interested committees to consider. Fundamentally, the problem is one of the inconvenience of changing established values rather than of the intrinsic merits of a particular standard.

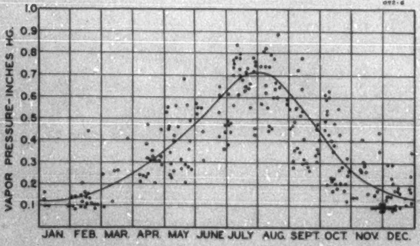

Figure 6. Humidity conditions at the Sharon high-voltage laboratory for outdoor tests, 1936–38

An undesirable situation prevails in connection with wet flashover testing. AIEE standards for circuit breakers and for transformers call for wet testing of bushings with a precipitation of 0.1 inch

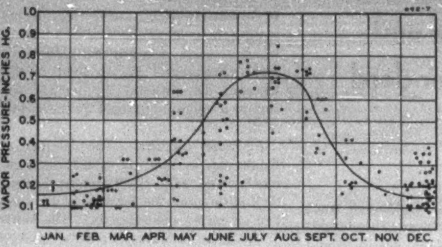

Figure 7. Humidity at the Trafford laboratory for indoor tests, 1934–38

per minute and a resistivity of 12,000 ohms per centimeter cube. AIEE standards for insulators specify wet flashover testing at a precipitation of 0.2 inch per minute and a water resistivity of 7,000 ohms per inch cube. AIEE standards for lightning arresters specify at least 0.1 inch of water per minute with the resistivity of 5,000 ohms per inch cube. The IEC groups have discussed standardizing on 3 millimeters per minute precipitation and 9,000–10,000 ohms per centimeter cube resistivity. A committee has been appointed to study and report on this situation and it is hoped that a simplification of testing procedures will result.

Summary

Reference values in present use are partly a product of history and were partly selected as a result of analysis. In some cases they represent average conditions and sometimes they do not. For certain applications different standardizing groups use different values and co-operative activities are thereby hindered.

An attempt has been made here to show the relation of reference values to variations found in practice. In most cases correction factors are available to correct measured values to standard conditions. The importance of correction factors is shown by figure 8 which gives the correction factor for humidity for the 60-cycle flashover voltage of suspension insulators. This indicates a correction of 16.5 per cent for tests made at 0.1 inch vapor pressure, a common condition in the winter months. Hence, from this point of view the selection of reference levels to minimize correction factors is to be recommended.

Attention is called to existing conditions, particularly where they are not conducive to easy comparisons of testing data and to simple testing procedures. It is hoped to stimulate the study of the problems involved and to assist present and future standardizing bodies in avoiding the confusion of the past and in organizing further work on a rational basis. At best all reference values and specified testing ranges must be a compromise for broader variations encountered by equipment under service conditions. Therefore, it seems reasonable to minimize the number and the ranges of the reference conditions.

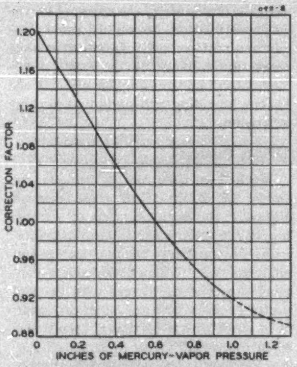

Figure 8. The importance of correction factors is indicated by the 20-per-cent spread in flashover voltages for the changes in absolute humidity indicated in figures 6 and 7

Humidity correction factors for 60-cycle flashover of rod gaps and suspension insulators; multiply measured kilovolts at humidity of abscissa by the correction factor

Standard humidity 0.6085 inch (15.45 millimeters)

Rating of Potential Devices and Suggested Material for a Standard

J. E. CLEM
FELLOW AIEE

P. O. LANGGUTH
ASSOCIATE AIEE

THERE has been an evident need for an exposition of the factors relating to the rating of capacitance potential devices and to their application. It is our intention to review this situation indicating the several limitations which govern ratings and application, and to offer material which may be used in the preparation of standards for potential devices. Vacuum-tube equipment is not covered. The authors were requested by the AIEE relay subcommittee to write a paper outlining the basis of rating for the purpose of formulating standards.

Description of Device Circuits

The potential device may be defined as a voltage-transforming equipment used in conjunction with a high-voltage bushing or capacitor as a source of energy to provide a low voltage suitable for operating instruments and relays. The output voltage may be corrected by one of several means to obtain the desired instrument voltage and phase angle.

LINES OF DEVICES

Practice has resulted in two varieties of capacitance devices, one for operation with bushings having a capacitance tap, and one for operation with coupling capacitors such as used for carrier-current work. The former is commonly referred to as a "bushing-potential device" and the latter as a "coupling-capacitor potential device".

TYPES OF DEVICES

Practice has also resulted in two general types of devices as used with coupling capacitors, and they may be designated as "quadrature" and "in-phase", respectively. With the "quadrature device" the maximum output is obtained when the phase angle between the output voltage and the impressed line-to-ground voltage of the phase to which the device is connected through the coupling capacitor is approximately 90 degrees. With the "in-phase device" the rated output is obtained with these voltages substantially in phase. It is not essential, however, that the quadrature device always be adjusted for 90 degrees, and hence it may be more aptly termed "out-of-phase" device. It is essential that the in-phase device always be adjusted for the in-phase relation, to obtain rated output and performance. However in some cases, an in-phase device may be adjusted to obtain an angular shift at the expense of rating and performance characteristics.

DEVICE CIRCUITS

Much has been written about the theory of operation of these devices. Basically, the device consists of a transformer for voltage reduction and a reactance, or auxiliary burden, for phase-angle control. When used with a coupling capacitor the device may be connected in series with the main capacitor, or in shunt with a portion of it, whereas when connected to an apparatus bushing, the shunt arrangement only is used.

The most usual circuit arrangements are as shown in figure 1, (*a*)—(*f*).

Quadrature or Out-of-Phase Circuits. The circuit of figure 1*a* is the simplest and least useful and may be used when the phase angle of the secondary voltage is a matter of indifference and the load burden is exactly right to obtain the required voltage. If the load burden becomes disconnected the voltage rise will be limited only by the insulation strength of the transformer, or by the flashover of a protective gap. Its use should be discouraged.

Figures 1*b* and 1*c* are the circuits commonly used with the out-of-phase devices, and it should be noted that in figure 1*c* the auxiliary burden must include an inductive reactance to compensate for the capacitive reactance of C_2, if true quadrature performance is desired. The magnitude and phase angle of the output voltage is controlled by adjusting the value of the auxiliary burden, which consists of resistance, inductance, and capacitance. If the load burden becomes disconnected the voltage will assume a value determined by the setting of the auxiliary burden.

In-Phase Circuits. The circuits of figures 1*d*, 1*e*, and 1*f*, are those commonly used with the in-phase devices, depending upon the location of the control, or series, reactance Z_s. The value of the series reactance is closely equal to the reactance of the auxiliary, or shunt, capacitor C_2 and is adjustable, mainly for phase-angle control. The capacitor C_2 is also adjustable in value to correct the power factor of the burden to unity. If the device secondary becomes short-circuited the voltage on the device primary will rise and be limited only by the losses or by the flashover of the protective gap.

Procurement of voltage at zero phase angle error primarily involves the use of a tapped bushing, tapped capacitor, or the equivalent, which in reality becomes a capacitance potentiometer. The tap voltage when supplying a totally capacitive burden will be in phase with the line-to-ground voltage of the coupling capacitor or bushing. A burden, other than zero power factor, will cause a phase displacement of the output voltage depending on its location in the circuit and the angular relation of the capacitor charging current and the burden current. This inherent phase displacement is corrected by the use of the inductive reactance Z_s.

Factors Affecting Rating

The rating of a potential device will depend upon economic and performance limitations that may be imposed. Factors involved in determining rating are:

1. Line voltage and frequency
2. Capacitance (electrostatic capacity) of the bushing or coupling capacitor
3. Permissible operating tap voltage on primary of device transformer
4. Insulation level of the device, and shunt or auxiliary capacitor
5. Characteristics and requirements of burden to be energized
6. Over-all performance requirements

AVAILABLE VOLT-AMPERES

The maximum volt-amperes available for potential-device operation depends on the line-to-ground charging current through the bushing or coupling capacitor and the operating tap voltage at which the potential device diverts this current for instrument use. Roughly the prod-

Paper 40-94, recommended by the AIEE committees on protective devices and standards, and presented at the AIEE summer convention, Swampscott, Mass., June 24–28, 1940. Manuscript submitted April 24, 1940; made available for preprinting June 5, 1940.

J. E. CLEM is in the central-station engineering department of the General Electric Company, Schenectady, N. Y.; P. O. LANGGUTH is in the switchgear engineering department of the Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

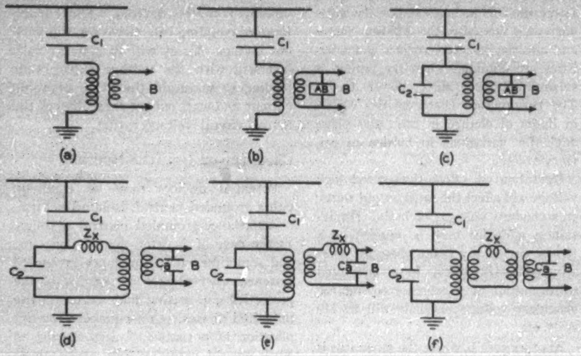

Figure 1. Typical circuits used for potential devices

C_1—Line-to-tap capacitance, sometimes coupling capacitance

C_2—Tap-to-ground capacitance, sometimes auxiliary capacitance, sometimes shunt capacitance

B—Useful burden

AB—Auxiliary burden for control

C_a—Power-factor-correction capacitance

Z_x—Series reactance for control

uct of these two quantities represents the maximum volt-amperes available from the transmission line. Practical considerations place a limit on the charging current and operating tap voltage. The voltage rating of the bushing, or the actual carrier coupling, fixes the capacitance. The operating line voltage and frequency determine the charging current that passes through this capacitance.

Watts Output

The output in watts of a potential device may be more accurately expressed:[1]

$$W=2\pi f C_1 E E_2 \sin\alpha - K$$

where f is the system frequency, C_1 is the capacitance line to tap, E and E_2 are respectively the line and tap voltage to ground with the angle α between them. K represents the loss in the device network. The actual rating of a device is somewhat less than the maximum theoretically available to insure satisfactory operating performance. The term $2\pi f C_1 E$ is the charging current and term E_2 is the operating voltage at which the potential network is normally energized. This voltage usually dictates the insulation level of the transformer and the shunt or auxiliary capacitor which will be used in the circuit.

Effect of Series Reactance

The use of series reactance for phase-angle control (in-phase device) will affect the transformer operating voltage and the resultant voltage on the auxiliary, or shunt, capacitor. The circuit may be analyzed by several methods. However, without going into detail, the network resolves itself into an essentially parallel resonant circuit wherein the bushing or coupling capacitor capacitive reactances are fixed and the equivalent inductive reactance may be varied. The operating tap voltage will increase as the inductance in the circuit is increased, up to the point of resonance, for any fixed load impedance. The rating of a device must not be such that will result in a voltage across the tap and transformer in excess of their individual insulation ratings.

Protective Gap

A protective gap is connected across the tap circuit or transformer primary to provide overvoltage protection in service, and when so protected the device should be able to withstand the overvoltages to which the coupling capacitor or bushing may be subjected. The setting of this gap must be co-ordinated with the normal-frequency voltage that may be obtained during the fault period and with the voltage rating of the component parts of the circuit to be protected. The gap should not operate at less than twice normal voltage at normal frequency, otherwise incorrect voltage may be imposed on the relays. Thus the setting of an insulation level for the component parts of the device will depend on the maximum normal operating voltage of the tap circuit or potential transformer, which in turn will govern the output of the over-all equipment for a given voltage class of bushing or coupling capacitor. Naturally economic factors will also affect the setting of the insulation level and ultimate size of the equipment.

Burden Requirements

The requirements of the burden to be energized, such as phase angle displacement of the voltage and permissible ratio error will affect the required characteristics and rating of the device. For instance, if voltage indication only is required at normal operating voltages, device regulation and phase-angle displacement are of no concern and the simplest form of device would be satisfactory. On the other hand, if certain types of high-speed relays are to be energized a much more accurate device will be required. This latter type of burden requires an accurate reproduction of the primary voltage both as to phase angle and ratio over a large range of line voltage and secondary burden. Nonlinear burdens represent a special case and their use leads to instability of the combined device and burden circuit for certain conditions of operation.

Performance Features

The over-all performance of a device includes:

(*a*). *Performance Characteristics*

1. Regulation, or change in ratio and phase angle, with variation in burden, at constant applied voltage.

2. Regulation with variation in applied voltage, at constant burden impedance.

Note: The regulation is usually given on the basis that the device is initially adjusted for normal voltage and burden impedance.

(*b*). *Transient Characteristics*

The transient characteristics consist of the rapidity and fidelity with which the device follows changes in the system voltage, and the freedom from instability under normal and fault conditions.

Regulation

The ratio and phase-angle performance of a device may be represented by:[2]

$$E_b=E_{bo}-I_bZ \qquad E_{bo}=\frac{A}{n}E_h$$

where E_b and I_b are the burden voltage and current respectively; E_{bo} the no-load voltage; Z the total equivalent potential device impedance; E_h the line-to-ground voltage, A the relation between certain impedances, and n the ratio of the potential-device transformer. These relations show that increased burdens on a given device generally result in increased ratio and phase-angle errors. This is due to the increased range of voltage on the potential device or tap circuit and to increased losses in the potential network.

Transients

Transient performance depends on the constants of the potential network used, the power factor, and type of the burden energized. All of these are interrelated with the device rating and the excitation requirements of the potential network.

Effect of Temperature Changes

The effect of temperature changes on the performance of potential devices may be considered in two steps: the effect inherent in the device itself; and the effect resulting from the changes in burden characteristics due to temperature changes. In the case of the in-phase device the temperature effect is practically negligible from either consideration for the usual conditions of operation. For the case of the out-of-phase device the inherent effect is also negligible except in regard to the coupling capacitance (auxiliary or shunt capacitance not used) for which a change of $2^1/_2$ per cent may take place for a temperature change from −20 degrees to 130 degrees Fahrenheit. Changes in burden, including the auxiliary burden, due to changes in temperature affect the performance in accordance with the characteristic curve.

Table I. Maximum Ratio and Phase-Angle Deviation With Variation in Applied Voltage

Per Cent Primary Voltage	Class A		Class B		Class C	
	Ratio (Per Cent)	Angle (Deg)	Ratio (Per Cent)	Angle (Deg)	Ratio (Per Cent)	Angle (Deg)
110	±1	±1	± 2	± 2	±2	± 5
100*	±1	±1	± 2	± 2	±2	± 5
85					±5	±10
25	±3	±3	± 6	± 6		
5	±5	±5	±12	±12		

* Device to be initially adjusted within these limits.

Basis of Rating

Potential-device rating is expressed on definite primary and secondary voltages, the watts output, and the performance characteristics. The primary voltage ratings are the standard high voltages such as 115 kv, 138 kv, etc. The corresponding secondary voltages are 115 and/or 66.4.

The output rating of potential devices is given in watts, instead of volt-amperes as is customary for potential transformers. This is done because the watts output is actually the limiting factor and also the best performance characteristics are obtained when the burden is substantially at unity power factor. The performance characteristics consist in limits of change in ratio and phase angle for variations in burden or primary voltage.

Operation at other than rated high voltage will affect the rated output watts, or secondary voltage, or both. For instance, a device may be applied on a 138-kv circuit at a point where the operating voltage is 132 kv. In this case rated watts output may be obtained but the secondary voltage normally will be 110 volts, etc.

Another case is where the apparatus is operated at a circuit voltage corresponding to the next voltage class below normal insulation rating. For such a condition a special device must be used and the device output is derated in proportion to the reduction in primary voltage, and normal secondary voltages and performance characteristics obtained.

Effect of Bushing Capacitance

The low capacitance of apparatus bushings limits the charging current available for potential-device operation. Impulse characteristics of these bushings, and the apparatus in which they are installed, place a definite limit on the operating tap voltage and thus the capacitance of the tap for potential device operation. The higher-voltage bushings will have a larger charging current than the lower-voltage bushings and thus the bushing potential device ratings will vary with the voltage class of the apparatus bushing. These output ratings will vary for each of the accepted standards of primary voltage.

Effect of Coupling Capacitance

Coupling-capacitor potential devices will have the same rating for any voltage class and in general it is higher than for bushing potential devices. The capacitance of coupling capacitors for the various voltage classes will in general vary inversely with the voltage rating thus tending to maintain the same charging current and watt output regardless of the normal circuit voltage rating.

Grounded or Isolated Neutral

Potential devices may be used on either grounded-neutral, isolated-neutral, or impedance-grounded neutral systems. In the case of isolated-neutral systems, and sometimes for impedance-grounded systems, overvoltages in excess of the protective gap setting may occur on the unfaulted phases. Consequently the application of potential devices should be given special consideration under these conditions.

Choice of a Potential Device for Relaying

The in-phase device should be used where the following forms of relaying are involved: ground directional, phase directional, carrier pilot, pilot wire, distance.

The out-of-phase device may be used for any one of the following forms of relaying: ground directional, balanced current with voltage restraint, undervoltage or overvoltage. It should be noted that most directional ground relays are arranged for operation from in-phase devices. If an out-of-phase device is used, a change in the voltage circuit of the relay is generally necessary.

Ratio and Phase-Angle Characteristics

The potential device should be chosen having ratio and phase-angle accuracy commensurate with the degree of accuracy required of the relaying. Generally, the accuracy of any in-phase device is suitable for all except possibly some forms of distance relaying.

In the case of distance relaying using reactance-type elements, errors in current and voltage sources introduce the following error in distance measurement:

$$\text{Per cent error} = 100\left[1 - \frac{K_c}{K_p}\,\frac{\sin(\phi+\theta_p-\theta_c)}{\sin\phi}\right]$$

where

K_c = ratio correction factor of current transformer
K_p = ratio correction factor of potential device
ϕ = power factor angle of line
θ_p = phase-angle error of potential device (positive if leading)

Table II. Maximum Ratio and Phase-Angle Deviation With Variation in Burden

Per Cent Burden	Class A Ratio (Per Cent)	Class A Angle (Deg)	Class B Ratio (Per Cent)	Class B Angle (Deg)	Class C Ratio (Per Cent)	Class C Angle (Deg)
100*	± 1	±1	± 2	± 2	±2	±5
50	± 6	±4	±10	± 5	**	**
0	±12	±8	±20	±10	**	**

* Device to be initially adjusted within these limits.

** Limits cannot be set on account of the varying relationship between values of useful and auxiliary burdens.

θ_c = phase-angle error of current transformer (positive if leading)

If the per cent error is a positive quantity, the distance measured will be less than the actual distance.

If impedance elements, which are not sensitive to phase angle, are used the error, usually small, can be expressed as:

$$\text{Per cent error} = 100\left(1 - \frac{K_c}{K_p}\right)$$

Appendix

Suggested Material for a Standard for Potential Devices*

There is a need for co-ordinated practice in regard to potential devices and in this appendix there is presented material suitable for standards. It is hoped this will serve as the basis for the formulation of potential-device standards by the Institute.

These suggestions have been prepared by the authors, reviewed by the AIEE relay subcommittee, and are presented here for the purpose of bringing them to the attention of the industry for comment.*

Scope

These standards apply to potential devices for use with coupling capacitors and/or bushings.

Terminology

POTENTIAL DEVICES

The potential device may be defined as a voltage-transforming equipment used in conjunction with a high-voltage bushing or capacitor as an energy source, to provide a low voltage suitable for operating instruments and relays.

Note: The term "coupling-capacitor potential device" may be used to indicate use with coupling capacitors, and "bushing potential device" indicates use with bushings.

RATIO

The ratio of a potential device is the overall ratio of the line-to-ground voltage of the phase to which the device is connected to the secondary voltage of the device. (It is not the turn ratio of transformers used in the network.)

REGULATION

The term "regulation" designates the change in ratio and phase angle when the burden is varied over a specified range (burden regulation) with constant primary voltage; or when the line-to-ground voltage is varied over a specified range (voltage regulation) with constant burden impedance.

Standard Ratio

The standard ratio shall be such as to give standard rated secondary voltages at rated burden when coupling capacitors are used at their rated voltage.

Classification

Potential devices are divided into two types and three accuracy classifications.

In-phase type—zero phase-angle adjustment—two accuracy classes

Out-of-phase type—30 to 150 degrees phase-angle adjustment—one accuracy class

TYPES

In-Phase. The secondary voltage shall be adjustable to be closely in phase and have correct ratio with respect to the line-to-ground voltage of the phase to which the device is connected, and to remain so for all values of applied primary voltage and secondary burden within the rating of the device, subject to the allowable deviations as herein stated.

Out-of-Phase. The secondary voltage shall be adjustable to the desired phase angle and of correct ratio with respect to the line-to-ground voltage of the phase to which the device is connected, subject to the allowable deviation as herein stated.

CLASSES

The accuracy classifications are as follows:

Class *A*—High accuracy, in-phase type

Class *B*—Lower accuracy, in-phase type

Class *C*—Out-of-phase type—for use with coupling capacitors only

Rating

The rating of potential devices shall include

1. Circuit voltage
2. Line-to-neutral voltage
3. Maximum watts output
4. Secondary volts
5. Frequency

Performance Characteristics

The standard characteristics of potential devices shall be based on

(*a*). Rated line-to-ground voltage of the circuit

(*b*). A frequency of 60 cycles

(*c*). Standard secondary voltages

(*d*). Specified burden

For the in-phase devices the performance characteristics shall be based on a unity-power-factor burden.

Rated Watts Output and Standard Secondary Voltages

For coupling-capacitor potential devices the rated watts output and standard secondary voltages shall be:

Class	Main Winding Watts	Main Winding Secondary Volts	Auxiliary Winding Watts	Auxiliary Winding Secondary Volts
A	150	115/66.4	75	115
B	100	115/66.4	50	115
C	75	115		

For bushing potential devices the standard secondary voltages shall be as given in the following table. The rated watts output is dependent upon the standard bushing and is being studied further. It is hoped to reach a conclusion in time to incorporate the results in the adopted standards.

Rated Circuit Voltage (Maximum Kv)	Line-to-Neutral Voltage (Maximum Kv)	Secondary Voltage (Volts)
115	66.4	66.4 or 115
138	79.7	66.4 or 115
161	93.0	66.4 or 115
230	132.0	66.4 or 115
287.5	166.0	66.4 or 115

Performance Specifications

VARIATION IN APPLIED VOLTAGE

The regulation with constant burden impedance for variation in applied voltage shall not be greater than given in table I.

VARIATION IN BURDEN

The regulation with constant primary voltage for variation in burden shall not be greater than given in table II.

Output at 50 and 25 Cycles

The output shall be reduced to 80 per cent for use on 50-cycle circuits. For use on 25-cycle circuits a special design is required.

Deviation of Circuit Voltage

Standard performance characteristics at proportionately reduced output ratings shall be maintained for a reduction in voltage from 5 per cent up to 20 per cent (that is, use of coupling capacitor of the next higher voltage class, in which case the watts output rating shall be reduced 20 per cent and a special design is required).

Power-Factor Correction

Coupling-capacitor potential devices shall be provided with a tapped capacitor in the secondary circuit as follows: class *A*, 115 volt-amperes in 3.75-volt-ampere steps; class *B*, 75 volt-amperes in 5-volt-ampere steps.

---

* Publication of this material with this paper authorized by the AIEE committee on protective devices at the Niagara Falls meeting, May 17, 1940.

In class *C* devices this feature is incorporated in the auxiliary burden.

Bushing potential devices shall be provided with tapped capacitor in the secondary circuit to correct the actual burden, assumed to be at 0.60 power factor lagging, to the rated burden at unity power factor, in 5-volt-ampere steps.

Adjustment Range and Steps

The maximum range over which adjustment shall be required and the maximum steps of adjustment shall be:

	Maximum Range of Adjustment		Maximum Tap Steps	
Class of Device	Ratio (Per Cent)	Phase Angle (Deg)	Ratio (Per Cent)	Phase Angle (Deg)
A	±5	±5	1	1
B	±5	±5	2	2
C	*	30–150	2	5

* Not specified.

Protective Gap and Grounding Switch

A protective gap set at not less than twice the maximum steady-state operating tap voltage shall be provided. A switch shall be provided for grounding the device primary.

Overvoltage Operation

Devices shall be capable of momentary operation with rated burden at circuit overvoltages not exceeding two times normal line-to-neutral voltage without becoming unstable.

Insulation Level

The insulation level of potential devices, and shunt and/or auxiliary capacitors, etc., in the primary circuit, shall be the same as used for instrument transformers of corresponding voltage class. The secondary winding, capacitors, etc., in the secondary circuit shall receive a test of not less than 2,500 volts, in accordance with instrument-transformer practice, proposed ASA Standards for Transformers, C57, page 34, table 7.

A Method for Detecting the Ionization Point on Electrical Apparatus

G. E. QUINN
MEMBER AIEE

WHEN any part of the air path included in the insulating circuit of a piece of electrical equipment is overstressed, ionization occurs. The critical value of voltage is a function of the nature of the remainder of the dielectric circuit, the manner of use, surface conditions, the proximity of grounded conducting bodies, the temperature, and in some cases, the relative humidity. Ionization in air causes the formation of small quantities of ozone and oxides of nitrogen. The presence of ozone leads to accelerated aging of insulating materials, especially organic materials such as varnished cambric and paper. The oxides of nitrogen may combine with water to form nitrous and nitric acids which attack cellulose materials and metals. While increasing temperature tends to decrease the voltage at which ionization occurs or to increase its severity at a given voltage, this effect is somewhat offset by the fact that the acids formed are decomposed at temperatures above 80 degrees centigrade. Under certain conditions increased humidity on the other hand not only causes more severe ionization at a given voltage but increases the severity of the action on the cellulose insulation or metal parts which may be present. Nonleaded cables have been known to fail in a few years when subjected to apparently mild ionization under high-humidity conditions. Ionization produces radio interference either by direct radiation or by conduction along the supply circuit or some paralleling circuit.

The minimum voltage at which ionization occurs on a piece of electrical equipment is of interest to both manufacturer and user. The necessity to arrest this condition and not wait until ionization is visible or audible has long been obvious with the result that a number of methods have been proposed for the determination of the voltage at which ionization occurs.[1–8] The method most commonly used at present is probably the one given in the "Report of the Joint Coordination Committee on Radio Interference of the EEI, NEMA, and RMA". Using this method the "radio noise influence voltage" of the equipment under test is measured and it is therefore essentially a radio-interference test. It is, however, satisfactory as a means of detecting the voltage at which ionization occurs on apparatus which can be tested at locations not subject to stray interference. It is often necessary for this work to be conducted under severe stray field conditions and it is the purpose of this paper to describe a simpler and less expensive method which may be used under such circumstances.

In the proposed method a cathode-ray oscilloscope is used to detect the pulses, surges, or damped oscillations introduced into the charging current by ionization

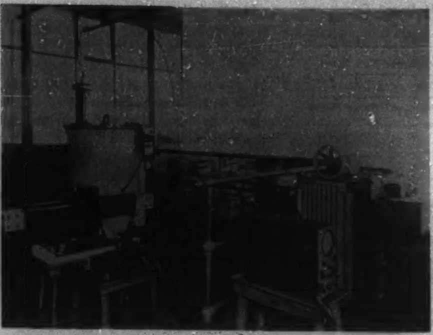

Figure 2. Test setup for determining ionization point on 5,000- to 5-ampere 15,000-volt current transformer

A circuit used with considerable success is shown in figure 1. A reactor L is inserted in the ground lead of the device under test and the voltage drop across this reactor is applied to the oscilloscope. Some time ago Lloyd and Starr[4] applied the drop across a resistor to an oscilloscope in a study of corona loss. While this method served its purpose it is not adequate for ionization-point determination. If this resistor is replaced by a suitable reactive shunt the usefulness of the method is greatly increased. Referring to figure 1 it will be noted that the reactive shunt is made up of a four-millihenry radio-frequency choke in series with a four-henry honeycomb-wound coil. This combination of impedance is used in order to obtain maximum deflection of the ionization components of current on the oscilloscope. The radio-frequency choke has a distributed capacitance of about one micromicrofarad and produces maximum drop for the high-frequency components of the ionization current while the four-henry coil is effective on the lower-frequency components. A blocking capacitor C is used in series with the oscilloscope in order practically to eliminate the test-frequency current appearing on the screen thus making it more readily possible to detect the first evidences of ionization. In addition, the oscilloscope may be operated with constant amplification as the voltage on the apparatus under test is increased.

A loading capacitor is connected in parallel with the device under test to provide a low-impedance path for ionization currents produced. By disconnecting this capacitor a simple means is provided for checking whether the oscilloscope is indicating ionization produced by the device under test or ionization inherent in the test setup. If the indication on the oscilloscope is due to ionization currents produced by the device under test, the indications will decrease. If it is due to a faulty test circuit the indications will increase because the short-circuiting effect of the capacitors will no longer be present.

The oscilloscope is a standard model with self-contained amplifiers and the sensitivity is usually set for 0.005 inch per millivolt deflection of the beam. It has been found that further increase in sensitivity increases the magnitude of the indication only, without appreciably decreasing the voltage at which oscillatory discharges are first detected.

In setting up this equipment, care should be taken to have all high-voltage connections free from sharp corners and edges in order to prevent ionization from these sources. Ground connections should be solidly made and capable of carrying the full short-circuit current of the testing set. In addition, a film gap of low capacitance should be connected as shown in figure 1 for further protection of the operator. Figure 2 is a photograph of a typical test setup, and shows a 15,000-volt 5,000-ampere current transformer under test. A shielded lead is shown connecting the oscilloscope to the reactive shunt. The two coils which make up the reactive shunt L will be noted on the table in front of the current transformer.

In using this setup the voltage applied to the device under test should be increased in about 200-volt increments and the oscilloscope observed at each value for indications of ionization. The sweep circuit of the oscilloscope should be adjusted for the test-circuit frequency or some submultiple thereof in order that the trace of the screen be stationary. The oscillatory discharges which accompany ionization appear superimposed on the charging current.

The definiteness with which the ionization point can be determined using this circuit can be seen in figure 3. The device under test in this case was a 3,000-volt lightning arrester. The marked difference between the oscilloscope traces obtained at 200-volt increments leaves no doubt as to the point of inception of ionization. These traces were obtained using a sensitivity of 0.005 inch per millivolt. Though the ionization point is not always as sharply defined in all pieces of equipment, it has been found that if the sensitivity is increased sufficiently oscilloscope traces similar to those shown on this figure may be obtained on any piece of equipment. The voltage at which ionization is detected at greatly increased sensitivity has been found to be not more than 200 volts below the value noted by a trained observer when the oscilloscope is set for normal sensitivity.

Figure 4 is an oscilloscope trace of ionization encountered at 6,000 volts on a 5,000-to-5-ampere 15,000-volt current transformer. The test circuit and sensitivity were the same as those used in obtaining the traces shown in figure 3.

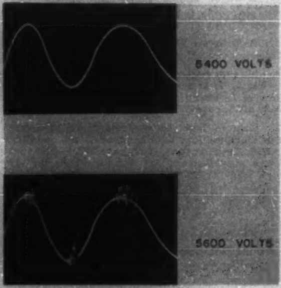

Figure 3. Oscilloscope traces showing the point of inception of ionization in a lightning arrester

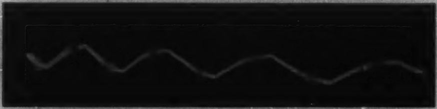

Figure 4. Oscilloscope trace showing ionization at 6,000 volts in a new 5,000- to 5-ampere 15,000-volt station-type current transformer

Table I. Results of Ionization Tests Using "Radio Noise Influence Voltage" Circuit and Cathode-Ray-Oscilloscope Method

Device Number	Type of Equipment		Minimum Voltage at Which Disturbance Was Noted			
			Increasing Voltage		Decreasing Voltage	
			Oscilloscope	Noise Meter	Oscilloscope	Noise Meter
1	Lightning arrester (repaired)		600	600	550	550
			500	500	500	500
			500	500	500	500
		Avg.	550	550	500	500
2	Lightning arrester (repaired)		2,000	2,000	1,750	1,750
			1,750	1,750	1,750	2,000
			2,200	2,200	1,750	1,750
		Avg.	2,000	2,000	1,750	1,850
3	Lightning arrester (repaired)		500	500	Less than 500	2,500
			600	3,000	800	3,000
			1,000	3,000	600	2,600
		Avg.	700	2,200	Less than 700	2,700
4	Current transformer (repaired)		1,300	1,300	800	950
			1,500	1,500	1,700	1,700
			1,800	1,800	2,650	2,650
		Avg.	1,550	1,550	1,700	1,750
5	Current transformer (new)		9,500	9,500	6,100	6,100
			9,000	9,000	4,500	4,500
			9,000	9,000	5,000	4,500
		Avg.	9,200	9,200	5,200	5,050
6	Current transformer (new)		4,700	4,700	4,800	4,800
			5,300	5,300	5,100	5,100
			4,900	4,900	4,700	4,700
		Avg.	5,000	5,000	4,900	4,900

Visual corona on this transformer was not detected until the voltage had been increased to 16,500 volts. Although this transformer is of recent manufacture, it can be seen from the figure that there is unmistakable evidence of ionization at a voltage considerably below the intended operating voltage to ground. This may be taken as evidence of a defect in this transformer since transformers of identical design and similar manufacturing processes, which were tested at the same time, showed no evidence of ionization below operating voltage to ground.

A series of tests comparing the oscilloscope method and the "radio noise influence voltage" method were made recently under normal laboratory conditions. Throughout these tests, intermittent stray disturbances were picked up by the radio-noise meter. At times these became so severe that it was found necessary to delay the tests until the stray interference decreased sufficiently to permit a satisfactory determination of the amount of interference generated by the device under test. In the case of the cathode-ray oscilloscope the external disturbances were identified by the nature of their appearance on the screen and therefore did not materially interfere with the progress of the test. External disturbances appeared on the oscilloscope as random oscillations at no definite point, whereas the high-frequency discharges from the device under test were always repeated at definite points on the screen since the frequency of the sweep circuit was set at a submultiple of the test frequency.

The results of the tests given in table I are reported as the minimum voltage at which the frequency discharges and radio interference were detected for both ascending and descending voltage on each device tested. The results of the test show that with the exception of one measurement obtained on current transformer designated device number 5 the oscilloscope indicated high-frequency discharges at or below the minimum voltage at which interference was noted on the radio-noise meter.

It will be noted that on the lightning arrester designated device number 3 high-frequency discharges were observed on the cathode-ray oscilloscope at voltages considerably below those at which interference was noted by the radio-noise meter. In order to study this further arbitrary values of the amplitude of the discharges were obtained. These extended from 0.05 inch at 200 volts to 3.70 inches at 4,250 volts. The radio-noise meter first detected interference at approximately 3,000 volts. The insensitivity of the radio-noise meter at the low voltages may have been due to a lack of interference at the frequency to which it was tuned.

In all of these tests the radio set was tuned to a frequency of approximately 1,000 kilocycles. It was found on an additional test that the noise measured by the radio-noise meter increased appreciably as the tuning frequency of the receiver was increased from 1,000 to 1,400 kilocycles with constant voltage applied to the device under test. This is contradictory to claims made for this method and indicates that further work should be done along this line.

The cathode-ray-oscilloscope method of detecting the ionization point of equipment has been used on many other types of electrical equipment including sections of bus, ground and test switches, disconnect switches, cables, porcelain pin-type insulators, and distribution transformers. All this work has served to illustrate the importance of a standard method for determining the ionization point of equipment and the desirability of treating this as the basic problem rather than using the secondary approach of radio noise.

While it is admitted that further work needs to be done in connection with the determination of ionization voltages, it would appear that the following conclusions may be drawn:

1. A cathode-ray oscilloscope used in connection with an appropriate air-core reactor will detect high-frequency discharges at or below the minimum voltage at which radio interference may be noted by the "radio noise influence voltage" method.

2. Since ionization when continued over a long period of time might have a deteriorating effect on the apparatus under test, it is important to know the minimum voltage at which it occurs.

3. The oscilloscope method is simple and satisfactory and is not affected by stray fields.

4. The oscilloscope method is dependable as a means of detecting disturbances over a very wide band of frequencies.

A New Measuring Instrument for Direct Current

H. T. FAUS
MEMBER AIEE

A. J. CORSON
ASSOCIATE AIEE

Synopsis: This paper describes the design of a new d-c measuring instrument of the permanent-magnet moving-coil type. Alnico is utilized as a magnet alloy and the design factors involved in the application of this material to instrument design are discussed. A moving system for use with the Alnico magnet system is described and the resulting instrument performance summarized.

RECENT advances in the development of alloys for permanent magnets have been of particular interest to the instrument designer, who utilizes these materials both in d-c instruments and in the damping systems of a-c instruments. While it is not proposed to describe in any detail the new aluminum-nickel-cobalt alloys, it may be stated that their distinguishing characteristics are high values of coercive force and available energy, as shown in figure 1. In instrument application, these qualities result in a magnet of short length and relatively high gap flux density. The use of one such material, an alloy of approximately 10 per cent Al, 17 per cent Ni, 13 per cent Co, and 6 per cent Cu, and remainder Fe, termed Alnico II, in instrument design is herein described. The instrument under consideration is of the permanent-magnet moving-coil type utilized primarily for direct current and voltage measurement, and the design is treated in some detail as very little material of this character has appeared in Institute publications.

The Magnetic Circuit

In permanent-magnet moving-coil instruments of conventional type, the magnet is either of horseshoe shape or U-shaped with soft-iron pole pieces. This construction is probably the most efficient that can be made for magnets of materials requiring a large ratio of length to diameter. When Alnico is used in a construction of this kind, the horseshoe becomes short and thick with the result that flux paths are of widely different lengths. Referring to figure 2, it is obvious that if *b* represents the correct length of the magnet for the given air gap, paths *c* and *a* are respectively too short and too long. As a result, the performance will not be equivalent to that of a magnet of equal weight and uniform section in which the entire magnetic flux passes through a path of length *b*.

4—Chromium magnet steel

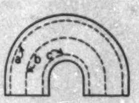

Figure 2. U-shaped magnet of approximate length-to-breadth ratio required for Alnico II

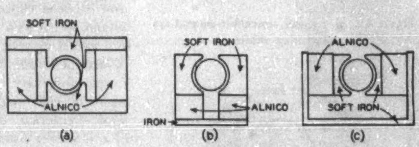

Figure 3. Alnico-magnet systems using soft-iron pole pieces

Perhaps the most obvious method of obtaining this result is by the use of short bars of Alnico in conjunction with bars and pole pieces of soft iron. A number of possible constructions of this type are shown in figure 3. These designs have a disadvantage, however, in that the leakage flux tends to be large, due to the large area of the soft-iron pole pieces. This leakage flux, aside from diminishing the air-gap flux, makes it necessary to shield instruments which are to be mounted close together, or near any magnetic material. The construction shown in *c* is least objectionable in this respect.

A condition of minimum leakage is obtained when the maximum magnetic potential is restricted to as small an area as possible immediately adjacent to the magnet pole face. This condition makes it necessary to have a soft-iron pole piece of minimum leakage area. Since the function of the soft-iron pole piece is to distribute the flux uniformly along the air gap, a condition essential to a uniform instrument scale, it is evident that the thickness may be reduced according to the amount of flux to be distributed. Assuming a uniform magnetic material, if the magnet is designed to give a uniform magnetic potential along the pole face no soft-iron pole piece will be necessary.

Referring to figure 4, it is seen that this condition of uniform magnetic potential is obtained by using a large number of bar magnets of equal lengths radially disposed about the core. This, however, is not a practicable method of construction and a similar result may be obtained by the use of sector-shaped magnets as shown in *b*. Reasonably uniform flux distribution may be obtained without using soft-iron pole pieces on magnets of

this shape, but it is advisable to use thin pole pieces attached to the face of the magnet since there may be slight fissures or inclusions in the permanent-magnet material. It is also difficult to magnetize these magnets in a perfectly radial manner. The flux tends to concentrate at the pole tips when they are magnetized as shown in figure 5, which method has been found to give the most nearly radial direction of magnetization.

Returning now to figure 4*b*, it will be noted that the area of cross section of the magnet varies in the radial direction, and that for any given cross section the area is roughly proportional to the sum of the useful flux in the gap and the leakage flux between the given section and the gap. The sector shape is thus conducive to operation at a uniform flux density in the magnet. This condition results in operation at a point at high available energy on the demagnetization curve, although the fact that certain dimensions were fixed, prevented operation at the point of maximum available energy.

In the application of this design it is found that true sector shapes are unnecessary. This is because (*a*) the increase in leakage flux with departure from the center of the system is not as great as the increase in magnet section thus obtained, (*b*) the outer corners of the sector (shaded area in figure 6) are partially ineffective due to difficulties in magnetization. The magnet may then be cut back as shown in figure 6 and the shaded area omitted, without appreciable loss in useful flux.

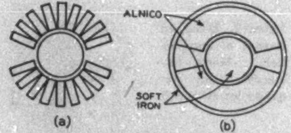

Figure 4. Elementary concentric-magnet system using Alnico

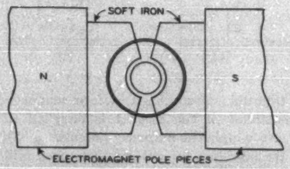

Figure 5. Apparatus for magnetization of concentric-magnet system

The Moving System

The design of a moving system (illustrated in figure 7) for use with concentric Alnico magnets does not differ in principle from conventional constructions, the theory of which is well known.[1] Several details of interest will, however, be described.

The general objective in the design of this part was a maximum mechanical factor of merit and speed of response at a definite current value. It has been shown[2,3] that the mechanical factor of merit (an index of the freedom from frictional errors) of an indicating system with vertical shaft and *V*-type bearing is

$$F = \frac{T}{W^{1.5}}$$

where

T = system restoring torque per unit deflection

W = weight of moving system including one-half the weight of the springs

The obvious function of the moving system is the movement of the pointer over a graduated scale. The pointer weight was, then, considered analogous to the "load" of other devices in the sense that the design originated at this member. To these values were added the weight of the balancing device, pivots, pivot supports, etc., all of which values depend upon the pointer weight, and the summation of which is the total fixed "load." It is obvious that this value must be kept at an absolute minimum consistent with mechanical durability, and overload capacity. The proper relationship between the fixed "load" and coil weight may be derived on the basis of current sensitivity in which case the torque will vary directly as the coil turns or coil weight. To satisfy the $T/W^{1.5}$ criterion, this leads to a value of coil weight equal to twice the fixed weight for a maximum factor of merit at a definite value of current.

It is of interest to note that the microwatt input for a given design (fixed winding space, constant space factor, flux density and torque) is theoretically independent of the current rating. Hence the coil resistance will vary approximately as the inverse square of the coil current and, without readjustment of other design constants, this resistance would achieve very high values for current values of a few microamperes and would involve impossibly small wire sizes. It is, therefore, advisable to lay out the basic design with a very liberal factor of merit to avoid impairment of accuracy when this factor is necessarily reduced as in microammeters. This procedure is facilitated by designing for as high a gap flux density as practicable, in which connection the high gap density obtainable with Alnico is of particular value.

* Corresponding to a decrement of 0.03.

of response, three factors are involved: (*a*) the moment of inertia, (*b*) the actuating torque, and (*c*) the damping torque. The ratio of moment of inertia to actuating torque determines the free period (although the relationship is not direct) hence, a high ratio of torque to moment of inertia is necessary for a low free period, and quick response. The required damping torque then follows from values already determined (that is, actuating torque and moment of inertia) although considerations must be given to the fact that the damping arrangement also adds to the weight and moment of inertia of the moving system.

It was necessary to give special consideration to the means of providing damping torque in this instrument. First, various values of damping torque were required for different applications depending on the actuating torque, and resistance of the circuit in which the instrument was to be used. This necessitated a flexible means of obtaining various damping constants. Secondly, the conventional aluminum frame (in effect a short-circuited turn on the moving system) was found to be inapplicable in a majority of ratings because in combination with the high gap flux density, overdamping resulted, even when the thickness of the frame was reduced to a minimum. The desired result was obtained by the use of damper windings of turns and resistance determined by the characteristics of the instrument involved.

Table II. Performance of Concentric-Magnet Instrument

1. Frictional error (difference between ascending and descending scale readings) (per cent of full scale)	<0.1
2. Ambient temperature coefficient in per cent per degree centigrade

Figure 7. Moving system for use with concentric-magnet system

Mechanical Design

The concentric magnet element lends itself to simplicity of mechanical design. The individual magnets *A*, figure 8, are sintered, precision ground, then placed in a soft-steel ring and permanently locked together by the die casting *B*. This die casting includes suitable mounting bosses, scale-plate supports, and grooves for receiving the element subassembly *C*. The complete element with a section cut away to show the core construction is shown in figure 9 and a complete instrument is shown in figure 10.

Numerical Values and Performance Data

Attention is directed to table I, listing significant constants of a typical concentric-magnet instrument, designed in accordance with the principles outlined in the preceding sections. A comparison of the total magnet flux and air-gap flux with maximum and minimum magnet sections will show that the magnet is operated at reasonably uniform density. A comparison of these constants with those of U-shaped magnet designs would be of value but the wide variation in design practice makes such a comparison impracticable. While a leakage of about one-half the total flux seems high, it should be remembered that the leakage flux is taken care of by taper in the magnet section, hence it does not subtract from the effectiveness of the design. So far as the authors' observation has extended, a useful air-gap flux density of 2,600 gausses in indicating instruments has been equalled only by using cobalt-steel magnets of very liberal proportions.

The particular moving system described is intended for use in a millivoltmeter having an accuracy rating of one-half per cent of the full-scale reading. The allowable energy input and hence the mechanical factor of merit of this instrument is relatively large and the response time is short. Where the allowable energy input is more limited, as in microammeters, the mechanical factor of merit will necessarily be less, although it must be consistent with the accuracy rating of the instrument involved.

Considering next the performance data in table II, it is noted that the frictional error is not observable, a statement which can be applied to any satisfactory design with vertical shaft and good bearing construction. In tabulating the temperature coefficients, influences causing an increase in deflection with a temperature rise are called positive, while those values causing a decrease in reading are negative. Various observers[4] have reported temperature coefficients for Alnico of the same order of magnitude as those obtained for chrome magnet steel. The temperature effect is apparently not exactly linear, hence the tabulated value is an approximation over the working range of the instrument. The control spring has, in general, a positive coefficient of greater magnitude than the magnet, resulting in a net positive coefficient for the element. In many applications, this is an advantage in that it partially cancels the negative coefficient of the electrical circuit.

The temporary error caused by stray fields is extremely small due to the self-

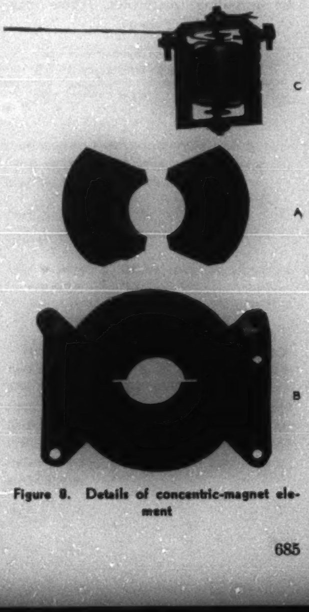

Figure 8. Details of concentric-magnet element

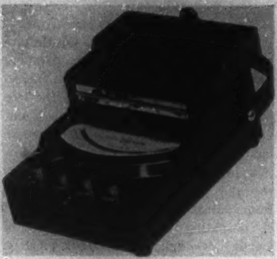

Figure 10 (right). Concentric - magnet voltmeter, completely assembled

shielding effect of the steel ring in the magnet system. In addition, the permanent error due to the application of the field is small since Alnico is relatively insensitive to external demagnetizing influences.

Data relating to the aging of permanent magnets are of limited value unless test conditions simulate service conditions very closely, and both the metallurgical and magnetic history of the material are known. A general review of the data accumulated to date in connection with this development indicates a normal aging under laboratory conditions of 0 to 2 parts in 1,000 during the first year, after which the aging curve flattens out and no noticeable change occurs. This applies to material which has been stabilized by a temperature cycle and a-c demagnetization. The aging curve is not improved, apparently, by annealing treatments. These magnets are very resistant to effects of subsequent temperature cycles and vibration incidental to service. These properties, and the insensitiveness of these magnets to external demagnetizing fields, make Alnico very well suited to this application.

Conclusion

The development of a new d-c instrument element has been described. As a result of careful consideration of the properties of Alnico as a permanent-magnet material, a compact design has resulted, characterized by inherent self-shielding and high gap flux density. These characteristics make possible instruments of small size, having sustained accuracy and high sensitivity. In addition, the element itself is particularly suited to incorporation in apparatus where space is at a premium.

The Rectifier Calculus

W. MELVIN GOODHUE
ASSOCIATE AIEE

Synopsis: The more involved rectifier-circuit problems, now becoming important because of the increasing magnitude of rectifier loads, can be most readily solved by the rectifying mathematical operator presented in this paper. Even with the more elementary problems, the final numerical computations are more simple in form than is usually obtained when conventional methods are used, since a lesser number of integrals and trigonometric functions are involved. In this paper, application is made to various rectifiers supplied with unbalanced power-line electromotive forces; also some elementary applications of the more simple formulas are included.

INITIAL efforts in rectifier engineering have quite naturally been directed toward mechanical design. But as the proportion of industrial power load carried by rectifiers is becoming large, due to electrolytic plants (electrochemical industries) and other new applications, it is important to be able to solve the more difficult circuit problems without excessive labor.

The rectifier becomes an important unit in a large system. As is well known, large systems may become unbalanced, short-circuited, fall out of synchronism, develop a local fault etc. Although under balanced conditions and sinusoidal electromotive forces, rectifier operation may be computed by conventional methods, under unbalanced conditions, or nonsinusoidal electromotive forces, the conventional methods become extremely intricate and laborious. Particularly in a large system, containing rectifier units, the system electromotive forces and degree of unbalance may be unknown, and since the rectifier units cannot be treated as ordinary three-phase impedances, solution is almost impossible by conventional methods. Only by gradual evolution of a more promising tool of analysis, such as the rectifier calculus presented in this paper, can the solution of such problems be hoped for.

In a restricted sense, rectifiers may be considered nonlinear. But the new theorem will reduce a nonlinear operator to what is for practical purposes a *linear expansion*. The result permits of easy calculation.

Because of the wide scope of the subject, a single paper can cover thoroughly only a single field of application, presenting the *theorems most suited to that field*. In this paper, the calculation of the output of unbalanced rectifiers has been chosen as the field of application.

In order to illustrate, a simple problem of unbalance in the polyphase a-c supply voltage will be considered. For example, in figure 1*a* is shown the no-load voltage output wave of a three-phase rectifier. Sections *A*, *B*, and *C* of this wave, which correspond to the three anode electromotive forces, e_a, e_b, e_c, are entirely dissimilar and unsymmetrical.

Even the intersection points 1, 3, 5, 1 are located at unequal heights and their timing is unsymmetrical. Furthermore the location of these intersection points is unknown.

To determine even the average value of such a wave by ordinary methods is complicated and laborious. It would be necessary to integrate separately each of the sections, and before the integration could be performed, the time of each intersection point, 1, 3, 5, 1 must be determined, as, for example, by finding the phase angle of the difference of the two sine waves concerned.

This new operator mathematics performs these integrations without recourse to the usual integration formulas involving integration limits. Hence, it is termed rectifier calculus.

Product Waves; The Operator Definition

Consider the two waves shown in figure 1*b*. *e* is *any* electromotive-force wave, which can be nonsinusoidal if desired, and $S_{\alpha\beta}$ is a unit rectangular wave extending between the points α and β on the axis. In figure 1*c* the curve $S_{\alpha\beta}e$ is the result of multiplying these two waves together, point by point. All portions of the original wave *e* are chopped off, except those between the limits α and β. Such a wave, denoted $S_{\alpha\beta}e$, will be referred to as a product wave. Each of the three sections *A*, *B*, *C*, in figure 1*a* is such a product wave.

This unbalanced wave, figure 1*a*, may now be expressed as the sum of three product waves, each similar to the wave shown in figure 1*c*:

$$S_{13}e_a+S_{35}e_b+S_{51}e_c \tag{1}$$

Such an expression may be transformed mathematically into new expressions, more convenient to integrate, and to perform other operations. Expression (1) may be abbreviated as follows:

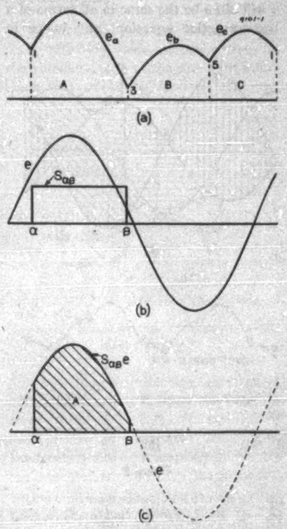

Figure 1

(*a*)—Unbalanced voltage wave
(*b*)—Components of product wave
(*c*)—Product wave

$$S_{135}e \tag{2}$$

where

1,3,5 = chopping limits such as abscissas 1,3,5
e = general letter for the electromotive forces involved, e_a, e_b, e_c

It is sometimes desirable to avoid mentioning the limits 1, 3, 5. These limits are determined by physical conditions such as valve action of the anode, grid delay, etc. If such anode physical properties are denoted as a group by a single index letter *y*, abbreviation may be carried further,

$$S_y^3e \tag{3}$$

Paper 39-101, recommended by the AIEE committee on electrical machinery, and presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939. Manuscript submitted June 10, 1937; made available for preprinting March 28, 1939; released for final publication August 14, 1939.

W. Melvin Goodhue is instructor in electrical engineering, Harvard University, Cambridge, Mass.

The author wishes to thank Professors H. E. Clifford and C. L. Dawes for their suggestions and for checking the manuscript; also R. M. Hutchinson, who prepared the drawings.

where

S = an operator
3 = number of phases (anodes)
e = letter indicating all phase electromotive forces involved
y = index letter indicating properties of the operator (anode and grid properties)

The advantage of this notation is that y will often be the same in all terms of a transformation equation, and hence in practice can be taken outside of the entire equation. The application to grid-controlled rectifiers and inverters, as well as to mechanical commutators, depends on the y principle, and will be given after the transformation theorem has been developed. In general, any number of phases, p, may be used with the operator S instead of 3, thus $S_y^p e$.

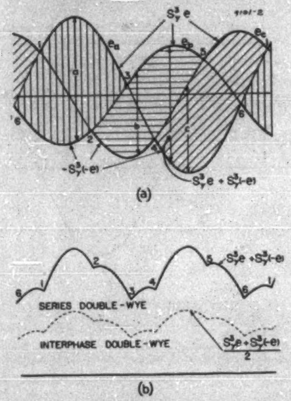

Figure 2

(*a*)—Graph of transformation theorem. $a = S_y^1 \times (e_a - e_b)$, $b = S_y^1(e_b - e_c)$, and $c = S_y^1(e_c - e_a)$

(*b*)—Resulting output voltage waves

Transformation Theorem

It may be proved by algebraic expansion (given in appendix) that,

$$S_y^3 e + S_y^3(-e) = S_y^1(e_a - e_b) + S_y^1(e_b - e_c) + S_y^1(e_c - e_a) \quad (4)$$

where

$S_y^3 e$ is the previous operator expression (3)

e_a, e_b, e_c are the anode electromotive forces of $S_y^3 e$

(Note: The form of this equation has been carefully selected to make impossible writing it for the general case of an odd total number of anodes, except by slight restrictions taken up in detail later in the paper.)

In figure 2*a* the waves involved in this equation are illustrated. The three-anode heavy wave $S_y^3 e$ is the same wave as shown in figure 1*a* and is the first term on the left-hand side of equation 4. The other three-anode heavy wave, 6-2-4-6, etc., is similarly constructed from the bottoms of the three electromotive-force waves e_a, e_b, e_c. It is denoted $-S_y^3(-e)$, since the electromotive forces are reversed, and it is plotted downward. If plotted upward, it would be the second term in equation 4, $S_y^3(-e)$.

The two terms $S_y^3 e$ and $S_y^3(-e)$ are characteristic of the well-known double-wye circuits in rectifier engineering, which involve two three-anode groups, *F* and *G*, figure 3*a*, phase displaced 180 degrees from each other. $S_y^3 e$ represents the output electromotive force of group *F*, and the other group *G*, with electromotive forces reversed, is naturally represented by $S_y^3(-e)$.

In an interphase double-wye (figure 3*a*) the output electromotive forces $S_y^3 e$ and $S_y^3(-e)$ of the two three-anode groups are paralleled through the interphase reactor, which averages them, giving one-half their sum, that is, one-half the quantity $S_y^3 e + S_y^3(-e)$. Both the sum and one-half the sum are shown as waves in figure 2*b*. Note there are six impulses per cycle.

Consider now the first right-hand term $S_y^1(e_a - e_b)$ in equation 4. e_a and e_b are indicated on figure 2*a*, and $e_a - e_b$ is the vertical distance *a*, between them. The exponent 1 on the operator S indicates a single impulse only, due to the single electromotive force involved, $(e_a - e_b)$. The index y indicates that the impulse is formed and controlled by an anode having the same physical properties as the anodes used on the left-hand side of the equation 4. As drawn in figure 2*a* for simplicity, the anodes of S_y^3, etc., have merely valve action, no delay being introduced by grid control or difficulty of anode pickup. $S_y^1(e_a - e_b)$ or *a* in figure 2*a*, therefore, will have in this case half-wave rectification (described below), since there is only one anode. From the left-hand point 6 to point 3, $e_a - e_b$ is positive, and $S_y^1(e_a - e_b)$ has the value $e_a - e_b$, indicated by *a* in the vertically shaded area. Elsewhere the term is zero, that is beyond point 3, because the single anode of S_y^1 cuts off. If sine waves are used, $S_y^1(e_a - e_b)$ is the positive half of the sine wave $e_a - e_b$.

Such half-waves as $S_y^1(e_a - e_b)$ are extremely easy to calculate even with unbalanced electromotive forces, and nonsinusoidal electromotive forces. For example, a half-sine wave has an average value equal to the peak value divided by π. With half-nonsinusoidal waves, the ratio of average to rms or peak value may be the same for all terms, and can be measured by single-phase instruments applied to the input alternating current.

The three half-wave terms on the right-hand side of equation 4 are indicated *a*, *b*, *c* in figure 2*a*. The boundaries of *a*, *b*, *c* are indicated by shading; there is no overlapping.

a extends from 6 to 3 only
b extends from 2 to 5 only
c extends from 4 to 1 only

It may be seen by inspection that the sum of the heights *a*, *b*, *c* is always equal to the height between the two major waves $S_y^3 e$ and $-S_y^3(-e)$. Hence the transformation theorem is made visible in distinct waves.

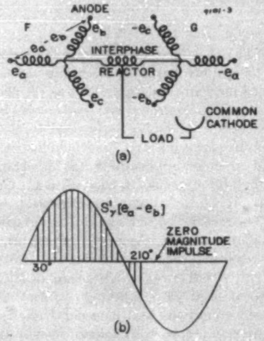

Figure 3

(*a*)—Ordinary double-wye circuit

(*b*)—S_y^1 term with 30-degree grid control

Other S_y^1 terms are similar, shifted to another phase of circuit

Numerical Application

Application will be best explained by an example of an unbalanced rectifier, with commutation overlap.

Example 1a. A double-wye rectifier is supplied with sinusoidal but unequal a-c voltages of such value that $e_a - e_b = 1{,}000$ rms volts, $e_b - e_c = 1{,}500$, $e_c - e_a = 900$. $e_a - e_b$ is the between-anode voltage, figure 3*a*, etc. Determine first the no-load voltage, assuming 20 volts arc drop, and assuming the interphase reactor can be properly excited.

Solution

$$\tfrac{1}{2}[S_y^3e+S_y^3(-e)]=\frac{\sqrt{2}}{2\pi}\times(1{,}000+1{,}500+900)-20 = 745 \text{ volts (average or d-c value)} \quad (5)$$

Explanation. The factor $^1/_2$ is inserted because with an interphase transformer, the two wyes supply the load in parallel. The $\sqrt{2}$ gives the peak value and the $1/\pi$ the average value. The three terms are added as required by equation 4. The arc drop, 20, is subtracted from every electromotive force, hence is conveniently left until last.

Note particularly that the intersection points of the waves (1, 2, 3, 4, 5, 6 in figure 2*a*) have not been determined, and neither is it necessary to integrate each section of wave, as it would be by the old methods, which are quite laborious for a problem of this type.

Regulation

Example 1b. Now determine the voltage regulation due to reactances in the anode and associated circuits in the rectifier of example 1*a*. The commutation reactances are $X_{ab}=0.1$ ohm, $X_{bc}=0.2$ ohm, and $X_{bc}=0.15$ ohm. The load current $2I=200$ amperes, and is well smoothed.

Solution

$$\tfrac{1}{2}[S_y^3e+S_y^3(-e)]=\frac{1}{4\pi}[0.1+0.2+0.15]100 =\frac{45}{4\pi} \text{ average or direct volts} \quad (6)$$

Explanation. The rectifier calculus may be used with nonsinusoidal electromotive forces and hence with reactance drops due to the nonsinusoidal currents. The average reactance voltage for one term on the right-hand side of equation 4 is

$$S_y^1(e_a-e_b)=\text{inductance}\times\text{average}\frac{di}{dt} =\frac{X_{ab}}{2\pi f}\times fI=\frac{IX_{ab}}{2\pi}=\frac{0.1}{2\pi}100 \text{ direct volts} \quad (6a)$$

where

I = peak current = 100
f = frequency
X_{ab} is measured between anodes

In this particular example, the two wyes, Sy^3e and $Sy^3(-e)$ deliver equal average voltages, and hence in spite of even harmonics present the interphase transformer operates, and the equation holds.

Note in example 1*b* that equation 4 can be successfully applied to regulation; with balanced rectifiers, it yields the conventional regulation formulas (see general theorem).

Grid Delay

In example 1*a* and figure 2*a* there is no grid delay. But the *y* in equation 4 permits the use of any physical system. To illustrate, assume a grid delay of 30 degrees on each anode in example 1*a*. That is the anode will not fire until 30 degrees after normal time. The grid delay applies also to the right-hand side of equation 4, so that from figure 3*b*,

$$S_y^1(e_a-e_b)=\frac{\sqrt{2}}{\pi}1{,}000\cos 30° \text{ average or direct volts} \quad (7)$$

$(\sqrt{2}/\pi)1{,}000$ is the value without grid delay. The limits must be moved to 30 and 210 degrees, the latter since the second half-cycle (zero anode volts) must be considered delayed also. An apparatus to produce this wave would consist of two anodes with anode voltages e_a-e_b and zero; it is still a half-wave, extending over a 180 degree interval. The average value involves the integral of a sine wave introducing cos 30 degrees. Hence the answer differs from the answer of example 1*a* in that everything except the 20 volts arc drop is multiplied by cos 30 degrees. This result is not surprising since the current lags 30 degrees. It is important to note, however, that the mathematics is still valid. The method can, of course, be applied to inverter circuits, which are special cases of grid delay.

General Theorem

Equation 4 may be extended to include any number of phases. Thus for *p* phases:

$$S_y^pe+S_y^p(-e)=\sum_1^p S_y^1(e_k-e_{k+1}) \quad (8)$$

where

e_k = the electromotive force of the *k* phase
e_{k+1} = the electromotive force of the $k+1$ phase
S_y^1 indicates single impulse (or half-wave) rectification
Σ indicates the sum of *p* terms
p = number of phases

This relation is very interesting since for practical purposes, equation 8 is a linear expansion because it involves Σ and e_k-e_{k+1}. The single-phase operator S_y^1 causes no difficulty because S_y^1 is independent of the number of anodes and has fixed numerical value for a given grid angle, supply voltage wave form, etc. Assuming unbalanced sine waves, grid delay α, unbalanced commutation reactances:

$$\text{average } S_y^pe+S_y^p(-e)= \beta\frac{1}{\pi}\left[(e_k-e_{k+1})_m\cos\alpha-\frac{IX_{ab}}{2}\right] \quad (9)$$

e_k-e_{k+1} = electromotive force between *k*th and $(k+1)$th anodes
m indicates peak value
X_{ab} = *k*th commutation reactance, measured between anodes
I = direct current to be commutated
$\beta=p$ for a balanced rectifier or $\sum_1^p$ for an unbalanced rectifier

Star Rectifiers

The theorem, equation 8, can be applied, with very moderate assumptions to star rectifiers, such as the commercial six-phase fork connection, figure 4. The reason for having any assumptions at all, is that the theorem is in double-wye or full-wave form $S_y^pe+S_y^p(-e)$ instead of merely star or half-wave form S_y^pe. Evidently there is something inherently fundamental in full-wave mathematics, not available in half-wave mathematics. Pure half-wave functions, such as S_y^pe alone, are already in simplest mathematical form and cannot be expanded, but merely denoted by the abbreviation S_y^pe. On the right-hand side of equation 8, each term, $S_y^1(e_k-e_{k+1})$ is already of the simplest form, S_y^pe, where $p=1$ (and of course $e=e_k-e_{k+1}$ etc.). Hence, it seems improbable that S_y^pe itself can be conveniently expanded without moderate assumptions, suitable to unbalanced rectifiers, as well as to normal rectifiers.

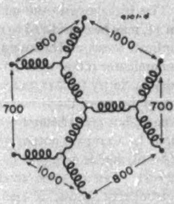

Figure 4. Six-phase fork connection, unbalanced supply

If the star rectifier has an even number of anodes, and the transformer has either interlaced secondary windings or is operating at light load, the rectifier may be considered full-wave, that is opposite anodes have equal and opposite electromotive forces, assuming symmetrical winding. In either case the leakage reactance does not interfere with the assumption.

Under these conditions,

$$S_y^pe=S_y^p(-e) \quad (10)$$

and equation 8 may therefore be applied. To illustrate:

Example 2. A six-phase fork-connection has between-anode electromotive forces (see figure 4) of 800, 1,000, and 700 rms volts, the supply being unbalanced. Determine the no-load output voltage, assuming sine-waves and 20 volts arc drop.

Solution

$$S^6e = {}^1/_2[S^6e + S^6(-e)] = \frac{\sqrt{2}}{\pi}[800+1{,}000+700]-20 \qquad (11)$$

Note π instead of 2π of example 1*a*.

Explanation. The first step is based on equation 10, $p=6$. Next, for the double-wye calculation there are six terms ($p=6$), and the average values of three of them are duplicated, due to full-wave conditions. The $^1/_2$ above in the middle of equation 11, may be considered to remove these duplicate terms, and hence π appears in the denominator rather than 2π.

In order to clarify further and to show the relation between these examples, a special example is given below:

Example 3. Compare output voltages of fork ($p=6$), double wye ($p=3$), single-phase ($p=2$). Assume same anode-neutral electromotive forces, E rms volts, balanced.

Solution

Fork: $$^1/_2[S^6e+S^6(-e)] = \frac{\sqrt{2}}{\pi}3(E) \qquad (12)$$

Double wye: $$^1/_2[S^3e+S^3(-e)] = \frac{\sqrt{2}}{\pi}\,\frac{3}{2}(\sqrt{3}\,E) \qquad (13)$$

Single phase: $$^1/_2[S^2e+S^2(-e)] = \frac{\sqrt{2}}{\pi}(2E) \qquad (14)$$

Explanation

Fork: between-anode electromotive force $=E$
six terms, with $^1/_2$ gives 3

Double-wye: between-anode electromotive force $=\sqrt{3}E$
three terms, with $^1/_2$ gives 3/2

Single phase: between-anode electromotive force $=2E$
two terms, with $^1/_2$ gives unity

Note that the double-wye gives $\sqrt{3}/2$ or cos 30 degrees times the average output voltage of the fork. The fork gives 3/2 the average output voltage of the single-phase rectifier. The peak inverse voltage of the double-wye is also cos 30 degrees times that of the fork. The values obtained by the new method are in agreement with values obtained by conventional methods. In this example the freedom of the rectifier calculus from trigonometric functions is apparent, together with extraordinary simplicity.

Odd Number of Anodes

In the previous section the star rectifiers considered had two or six anodes or in general an even number. But with an odd number of anodes the rectifier is half-wave, since opposite anodes do not exist. It is usually practicable though to compute the corresponding double-wye rectifier, illustrated below.

Assume the d-c output is independent of polarity of the a-c input (absence of input even harmonics).

This is incidentally one of the conditions for proper interphase operation. With this moderate assumption the average voltage is determined on a simple mathematical basis:

$$\text{average } S_y^pe = \text{average } S_y^p(-e) \qquad (15)$$

rather than by equation 10, for which p is even. To illustrate graphically, in figure 2*a*, the upper heavy wave S_y^pe has, by inspection, an equal and opposite average value compared with the lower heavy wave $-S_y^3(-e)$. In other words S_y^3e and $S_y^3(-e)$ have the same average value.

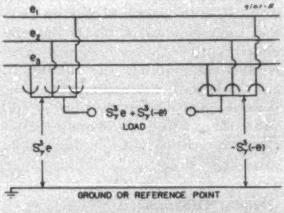

Figure 5. Full-wave three-phase "bridge" circuit

Physically the two wyes of figure 3*a* will have the same d-c output under normal conditions.

The method of application is similar to example 1*a*, since

$$\text{average } S_y^3e = \text{average } {}^1/_2\,[S_y^3e+S_y^3(-e)] \qquad (15a)$$

and the answer to example 1*a* is therefore also the output of a three-anode rectifier with the specified unbalanced electromotive forces.

Therefore, for commercial purposes, the new mathematics is applicable to rectifiers irrespective of the type of circuit used. Some very special circuits may, however, require the use of the equivalent star rectifier, being solved as a star.

Nonsinusoidal Waves

It has been stated that this method may be applied quantitatively to nonsinusoidal electromotive-force waves. Labor is saved, however, only if the nonsinusoidal waves are balanced. This permits various circuits to be compared rapidly without graphical or other wave-form labor, which is certainly not the case if the voltage waves must be integrated separately for each circuit, as with conventional methods. The development will, therefore, be for balanced rectifiers.

IN TERMS OF FORM FACTOR

Replace $\sqrt{2}/\pi$ for sine waves by $^1/_2K$ where K is the form factor (rms/average value of half-cycle loop) and the $^1/_2$ factor is for half-wave rectification (single-anode).

From equation 15

$$\text{average } S_y^pe = \text{average } {}^1/_2[S_y^pe+S_y^p(-e)] \qquad (15b)$$

Note: form factor cannot be used in presence of even harmonics, hence (15*b*) applies, having the same limitation.

Then from equation 9, assuming $\alpha=0$

$$\text{average } S_y^pe = p\left[\frac{(e_k-e_{k+1})rms}{4K}-\frac{IX_{ab}}{2(2\pi)}\right] \qquad (16)$$

Following equation 9, the reactance regulation has been included, to show the method.

Example 4. Compare the output voltages of double-wye and fork connections, for the same rms anode-neutral voltage, E, form factor $K=1.2$.

Solution. (Refer to equation 16)

Fork ($p=6$,

$$e_k-e_{k+1}=E): \frac{6E}{4K} \text{ direct volts, } K=1.2 \qquad (17)$$

Double-wye ($p=3$,

$$e_k-e_{k+1}=\sqrt{3}E): \frac{3\sqrt{3}E}{4K} \text{ direct volts} \qquad (18)$$

Answer

$$\text{ratio} = \frac{2}{\sqrt{3}} \text{ independent of form factor} \qquad (19)$$

IN TERMS OF WAVE FORM

The average value of e_k-e_{k+1}, half-wave rectification, grid delay α (and $180+\alpha$, see figure 3) may be denoted by H.

$$H \text{ replaces } \frac{(e_k-e_{k+1})_m \cos\alpha}{\pi} \qquad (20)$$

Hence equation 9 becomes,

$$\text{average } S_y^pe = p\left[\frac{H}{2}-\frac{IX_{ab}}{4\pi}\right] \qquad (21)$$

If example 4 is repeated, the ratio $2/\sqrt{3}$ will also be found, independent of grid delay α, since H is fixed for a given α, independent of p.

Bridge Rectifiers

A typical bridge circuit is the full-wave three-phase bridge, figure 5. By inspection, this consists of two wye rectifiers, and is in fact a series-double-wye circuit, the series connection replacing the interphase transformer.

Equation 4 or 8 is directly in bridge form, giving the voltage of any series-double-wye circuit. Hence, application does not differ materially from the examples given for the interphase double wye except that the output voltage is twice as great.

There are many involved subjects in the field of rectifiers, inverters, and grid control to which the rectifier calculus has been applied. In this paper, no attempt is made to discuss them, or even to introduce derivatives, integrals, and the corresponding operator treatment which would make the subject far too involved for an introductory paper.

The operator itself and its expansion theorem have been described without calculus, and a sufficient number of simple applications have been given to show that a new field of analysis has been opened to the engineer and mathematician. The ease with which the peculiar waves encountered in rectifiers and allied fields can be represented should recommend it to teachers and beginners as well as to experts. The ability to write a large number of circuit equations in one without introducing a laborious method or notation should be recognized.

A partial list of application fields, in which the subject has been developed, is as follows:

Inductive and capacitive loads on rectifiers
Rectifiers with d-c back electromotive force in load
Regulation of rectifier circuits
Alternating currents of polyphase rectifiers
Grid-controlled rectifiers
Inverters
Polyphase rectifiers, more than six anodes
Commutators, other than d-c machinery
Self-regulated rectifiers
Compounded rectifiers
Differential and transcendental equations

From the definitions, analyses, and applications which have been given in this paper, the following conclusions may be drawn:

1. The method saves much labor in the calculation of unbalanced systems.
2. Calculation of ordinary balanced systems is rapid. The method is, therefore, of general application.
3. Commutation overlap, grid delay, arc drop, and choice of circuit do not invalidate the method or cause inconvenience.
4. The method demonstrates the general linearity of rectifier mathematics, when expressed in terms of between-anode electromotive forces, which are more significant than anode-neutral electromotive forces.
5. By means of (4), all trigonometric functions are eliminated from fundamental formulas.
6. The operator does not assume a particular physical application such as grid-controlled rectifiers and may conceivably be applied to new systems.
7. A wave-form assumption is generally necessary only for a rectifier whose total number of anodes is odd.
8. It is easy to interpret circuits into equations and vice versa.
9. Methods of solution are rational, as distinguished from ingenious devices.
10. The method is inherently suited to multiple discontinuities. Some of the contemporary methods are primarily intended for single discontinuities only or for very simple combinations of discontinuities.

Appendix

Proof of Transformation Theorem

In the text, rectangular waves are used as factors in defining the operator. Properties of rectangular waves will be utilized in the proof.

By inspection of figure 6, the rectangular wave S_{14} is equal to the sum of sections S_{12}, S_{23}, S_{34} thus

$$S_{14}=S_{12}+S_{23}+S_{34} \qquad (22)$$

Now the rectified voltage term $S_y{}^1(e_a-e_b)$ may be expanded by means of the operator definition (equation 1) into a single product wave such as, $S_{14}(e_a-e_b)$. Then on substituting the value of S_{14} further expansion takes place.

$$S_y{}^1(e_a-e_b)=S_{14}(e_a-e_b)=(S_{12}+S_{23}+S_{34})(e_a-e_b) \qquad (23)$$

Similarly:

$$S_y{}^1(e_b-e_c)=(S_{34}+S_{45}+S_{56})(e_b-e_c) \qquad 24)$$

$$S_y{}^1(e_c-e_a)=(S_{56}+S_{61}+S_{12})(e_c-e_a) \qquad (25)$$

On adding the left-hand sides in order to build up equation 4, some terms on the right-hand side cancel, and the remainder may be grouped:

$$\begin{aligned}S_y{}^1(e_a-e_b)+S_y{}^1(e_b-e_c)+S_y{}^1(e_c-e_a) = {}&(S_{23}+S_{34})e_a+(S_{12}+S_{23})(-e_b)+\\&(S_{45}+S_{56})e_b+(S_{34}+S_{45})(-e_c)+\\&(S_{61}+S_{12})e_c+(S_{56}+S_{61})(-e_a) \qquad (26)\end{aligned}$$

Combining according to the principle of figure 6, $(S_{23}+S_{34})=S_{24}$, etc., the right-hand side may be abbreviated:

$$\begin{aligned}&S_{24}e_a+S_{51}(-e_a)+\\&S_{46}e_b+S_{13}(-e_b)+\\&S_{62}e_c+S_{35}(-e_c) \qquad (27)\end{aligned}$$

The vertical columns have the form, $S_{246}e$, etc., of one of the stages in the operator definition (see expressions 1 and 2). Therefore

$$S_y{}^1(e_a-e_b)+S_y{}^1(e_b-e_c)+S_y{}^1(e_c-e_a)=S_{246}e+S_{513}(-e)=S_y{}^2e+S_y{}^2(-e) \qquad (28)$$

The use of y on the right-hand side of the equation depends on the fact that the anode properties (value action, etc.) are referred always to the between-anode voltages, which are the same, e_a-e_b, etc., on both sides of the equation.

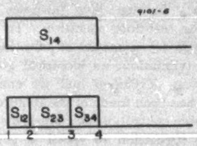

Figure 6. Rectangular wave expansion

This proof assumes that the electromotive forces are lettered in actual firing order. Should electromotive forces be such that firing order is upset, the lettering should be changed accordingly.

Discussion

For discussion, see page 1073.

Recent Developments in Speed Regulation

C. R. HANNA
MEMBER AIEE

K. A. OPLINGER
MEMBER AIEE

S. J. MIKINA
NONMEMBER AIEE

Synopsis: This paper deals with recently developed electrical speed governors in which a system stabilizing influence is incorporated by means of a governor response to time rates of change of speed. It is shown that the response to acceleration constitutes a powerful antihunting means which is anticipatory in action and offsets the effect of time delays in the regulated system. New designs utilizing electrical contacts are described, and a mathematical analysis is given for the determination of the conditions for stability of several typical regulated systems comprising assemblies of rotating electrical machinery.

THE PROBLEM of automatically maintaining constancy of speed in rotating machinery is frequently encountered, aside from prime-mover governing, in such applications as d-c drives for a-c generators whose frequency must be kept unvarying to a high degree of accuracy for signalling purposes or for exacting test-floor operation. To satisfy the need for a means of effecting such speed regulation, an electrical governor has been developed and an analytical study has been made of the requirements for stable control of the governed system.

The regulation of speed is generally effected by the application of corrective torques whose magnitude and direction, as well as duration of application, are controlled by a mechanism responsive to physical quantities which are affected by changes in speed. The following are the most important of the quantities which may be utilized for control of speed:

1. Position with respect to a member moving at the desired speed.
2. Viscosity forces due to a velocity gradient in fluid between moving and stationary parts.
3. Electromagnetic forces between moving and stationary parts.
4. The generated voltage of a generator.
5. The frequency of a voltage generator.
6. Centrifugal forces, whether acting on a solid mass or on a fluid mass in a pump system.
7. "Coriolis" forces, as in a precessing gyroscope, for controlling slow speeds too low for a directly connected governor of any other type.

Systems utilizing numbers 1 and 5 are not strictly speed-regulated systems, but rather position regulated because they maintain perfect synchronism with respect to a standard of reference. The types of regulator to be considered in this article are those in which the speed approaches perfect constancy, but still small percentage deviations are tolerated; in other words, perfect phase accuracy is not expected.

Whenever the corrective torques are subject to time delays, that is, whenever time lags occur between the initiation of a corrective stimulus and the final application of corrective torques, then, to secure good accuracy with stability of regulation, the governor must respond not only to a change in speed, but also to the time derivatives of this change, and notably to the first rate of change of speed. The mathematical analysis described here shows that in a speed-regulating system, a governor response to acceleration constitutes a powerful antihunting means which greatly extends the range of regulator amplification giving stable operation. The physical quantities available for sensing acceleration are:

(*a*). The force of acceleration of a mass.

(*b*). The velocity of change in length of a spring that is acted upon by forces proportional to the regulated speed.

(*c*). The voltage drop across an inductance when the current through it is proportional to the regulated speed.

(*d*). The current through a capacitor when the voltage across it is proportional to the regulated speed.

Principle of Contact Governing

The newly developed speed regulator functions by controlling an appropriate electric circuit, such as the field of a motor, by means of a movable contact acted upon by both centrifugal and angular acceleration forces.

The use of contacts for speed control had been limited heretofore to the regulation of fractional-horsepower series or shunt motors with moderate load-variation and speed-accuracy requirements. A typical regulator for small-motor application comprises a movable spring-biased contact which is subject to the centrifugal force of its own mass and which makes and breaks a slip-ring-connected field circuit respectively above and below the regulated speed. Such a simple governing element is severely limited, however, in power-handling capabilities and is totally inadequate for applications involving the accurate regulation, over a wide speed range, of machines having large time delays or in systems of cascaded machines controlling large power machinery. The presence of time delays in the corrective cycle will make the regulated system oscillatory, or even self-oscillatory under certain conditions, appearing as hunting if proper measures are not taken to stabilize the system.

To meet the severe regulation requirements imposed by such time delays, the new governor designs incorporate an acceleration response which, since it precedes a response to change in speed, is anticipatory in action and offsets the action of time delays within the regulated system. This is illustrated schematically in figure 1, which shows the principle applied to a governor consisting of one pair of contacts. In figure 1*a*, if the spring-biased contact is confined to motion in a radial direction only, the acceleration component of the force on the movable contact will not change the contact pressure and the response will be only that due to a change in centrifugal force on the contact as a result of change in speed.

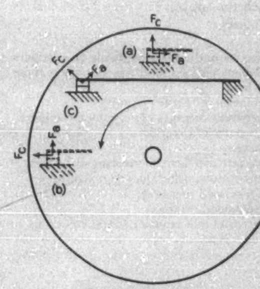

Figure 1. Schematic of simple contact governor

Paper number 39-95, recommended by the AIEE committee on electrical machinery, and presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939. Manuscript submitted October 10, 1938; made available for preprinting March 28, 1939.

C. R. HANNA is manager of the electromechanical division of the research department, and K. A. OPLINGER and S. J. MIKINA are research engineers, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The writers wish to acknowledge the valuable assistance given by S. Sentipal in working out many details of design in connection with this paper.

Conversely, in figure 1*b*, when the movable contact is confined only to motion in a tangential direction, the contact-pressure variation due to angular acceleration is a maximum and there is no contact response to a change in speed. With the contacts disposed in an intermediate position between these two extremes, as in figure 1*c*, both the centrifugal and the angular acceleration forces on the contact have components along the line of travel of the movable contact, and the resultant change in contact pressure is the algebraic sum of the changes produced by a change in speed and by its time rate of change.

At the regulated speed, the centrifugal force on the movable contact is equal to the biasing-spring force and a hovering condition at the contacts is established whereby a value of regulator resistance is developed sufficient to maintain the desired speed. The regulating action of such contacts when shunting a control resistance may be developed either through intermittent opening and closing or by changes in pressure between the contacts which can occur with practically no contact motion. In the range where no separation of the contacts occurs, but only changes in pressure, the contacts exercise a regulating function by virtue of the resistance-pressure characteristic of contacts subjected to contact pressure. An example of such a characteristic for a carbon-silver pair is given in figure 2, which shows the contact resistance as a function of the force with which the contacts are pressed together. It is apparent from this curve that the full range of resistance variation from an open circuit to a low resistance can be obtained with extremely small changes in contact pressure in the hovering region beginning with the inception of contact. Oscillograms of the contact current actually show that regulation is effected at frequencies of several hundred cycles per second in the hovering region where only contact-pressure changes occur, but no actual separation. This extreme sensitivity of hovering contacts may be used advantageously to secure great accuracy in regulating applications, but it may also be a source of difficulty by making the contacts susceptible to extraneous influences other than those produced by the regulated quantity, if adequate provision is not made for suppressing such influences. For example, if the simplified governor of figure 1*a* were mounted on a horizontally revolving shaft the contacts would be subject to a force of gravity that would reverse its direction along their line of movement once per revolution, producing a maximum change in contact pressure corresponding to twice the weight of the movable contact. The effect of such pressure pulsations, or of contact vibration in general, is to reduce the contact sensitivity. What might be termed the "contact amplification," or the ratio of change in regulating current to change in contact pressure, is reduced because larger changes in steady pressure are then required to produce a given change in regulating current.

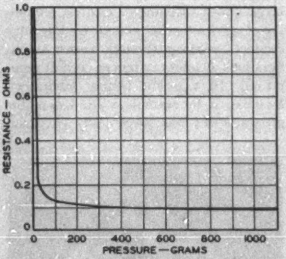

Figure 2. Resistance-pressure curve for silver-carbon contacts

The reduction in contact amplification due to vibration may be calculated quite simply for the case in which actual separation of the contacts occurs in the idealized example shown in figure 3. The "static" current-pressure characteristic of the contact pair of figure 2 when shunting a control resistance is shown in figure 3, with i_1 corresponding to an open contact condition and with i_2 for a closed contact, while the vertical line joining i_1 and i_2 at zero pressure corresponds to the hovering condition represented by the substantially vertical portion of the pressure-resistance characteristic of figure 2.

To simplify the calculation, a massless contact is assumed to be capable of moving through a negligibly small displacement, which is sufficient to make or break the circuit, while being subjected to a steady force P_s and an alternating force $P_a \sin (2\pi t/T)$. The average current as a function of P_s will then depend on the ratio of the time the contacts are open to the time they are closed. Therefore,

$$i_{avg} = \frac{i_1t_1 + i_2t_2}{t_1 + t_2}$$

where $t_1 + t_2$ = period of alternating force = T. To determine t_1 and t_2, we note that the contacts are closed when the resultant force on the movable contact is positive and open when it is negative.

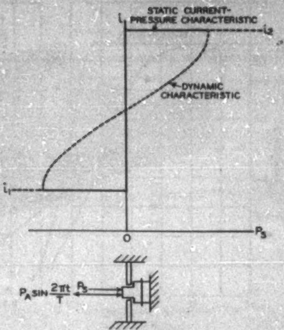

Figure 3. Effect of contact vibration in idealized case

The resultant contact force is

$$P = P_s - P_a \sin \frac{2\pi t}{T}$$

When $P = 0$,

$$\frac{2\pi\,{}_1t_0}{T} = \sin^{-1} \frac{P_s}{P_a}$$

and

$$\pi - \frac{2\pi\,{}_2t_0}{T} = \sin^{-1} \frac{P_s}{P_a}$$

Whence

$$t_1 = {}_2t_0 - {}_1t_0 = \frac{T}{2} - \frac{T}{\pi} \sin^{-1} \frac{P_s}{P_a}$$

$$t_2 = T - t_1 = \frac{T}{2} + \frac{T}{\pi} \sin^{-1} \frac{P_s}{P_a}$$

Therefore

$$i_{avg} = \frac{i_1 + i_2}{2} + \frac{i_2 - i_1}{\pi} \times \sin^{-1} \frac{P_s}{P_a} \quad (\text{for } P_s < P_a)$$

This relation is represented by the dotted line of figure 3 and shows a practically linear variation between current and steady contact pressure at the hovering condition of zero steady pressure. In this idealized case, the contact amplification was thus reduced from the infinite value for no vibration to that represented by the slope of the dotted curve with contact vibration. In an actual case, the conditions under which contact vibration occurs are complicated by inertia and impact effects and it is difficult to derive any quantitative relations for the effect of contact vibration. In the main, however, one may expect that reduced amplification will result from such a condition. This is illustrated in figure 4, which gives the results of measurements in a vibrat-

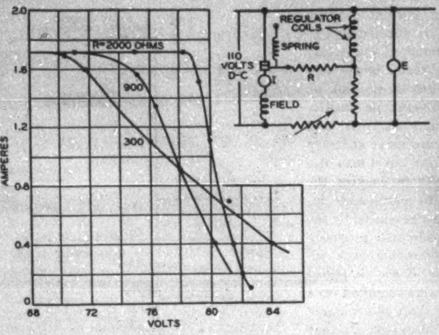

Figure 4. Amplification of vibrating regulator

Figure 5. Two-member governor on submarine signaling motor generator set

ing-contact type of voltage regulator. The curves of field current versus generated voltage are plotted for different values of the resistance *R* which determines the amount of vibration at the contacts. It is seen that as *R* is decreased and the vibration increased the amplification of the contacts, as measured by response in field amperes per volt of voltage deviation, is decreased.

The reduction in contact amplification as a result of vibration must be avoided when high regulation accuracy is desired. In certain cases, however, a lowered contact amplification is a definite advantage that may be purposely introduced. Such is the case, for example, in the governing of prime movers which must operate in parallel on the same load. To insure proper division of load at a given speed between the machines, their respective governors must produce a drooping speed-load characteristic in proper relation to each other, as determined by the required load division. With the contact type of governor, the speed-load characteristic produced may be readily varied to suit any requirement by means of vibration of the contacts.

New Governor Designs

The principal objectives which determined the design of the new governor were the preservation of contact amplification to insure high accuracy and the provision of adequate system stabilizing influences by means of anticipatory response. The design which was worked out to meet these requirements over a wide range of applications is shown in figure 5 as attached to a motor shaft. It consists of a gravity-balanced speed-responsive member which is pivoted on ball bearings about an axis through its center of gravity and perpendicular to the axis of the motor, and an acceleration-responsive member in the form of a flywheel mounted on ball bearings on the motor axis. The speed-sensing member is a cage-like structure supporting a pair of weights which give rise to a centrifugal couple tending to rotate the cage about its pivot axis. This rotation is restrained by a Z-shaped flat spring attached at its ends to the cage and at its center to a stub shaft which is rigidly coupled to the motor shaft. Two pairs of silver contacts are attached to the cage and flywheel in such relation that relative movement between the cage and the flywheel can make and break a slip-ring-connected external circuit. For a given direction of rotation only one pair of contacts acts in a control capacity, while the other pair provides the necessary reaction for the control-contact pressure. It is apparent that, in the absence of angular acceleration, the contact forces are equalized by the freedom of the cage and the flywheel to rotate about their pivot axes. During angular acceleration, this equalization is disturbed by the amount of torque required to accelerate the flywheel, and this torque is produced by a decrease in force between one pair of contacts and a corresponding increase between the other pair. This dependence of contact pressure on the cage position and on the flywheel acceleration prevails also at the regulated speed when a hovering condition is established by equality between the centrifugal couple on the cage and the spring torque.

When the direction of machine rotation is reversed, the effect of flywheel acceleration on contact pressure must also be reversed in order to maintain the proper anticipatory action. In the two-member inertia governor discussed above, a change in rotation is made possible simply by interchanging the control and reaction contact functions by means of a switch. The regulated speed may be changed by adjusting the amount of initial spring torque on the cage by means of a set-screw.

Practically unlimited contact life may be secured by keeping the contact voltage below the arcing limit of 10 to 12 volts and the current below one ampere. Long life may be secured for voltages above the arcing limit if the current is of the order of 0.1 to 0.2 amperes or less. Where a certain amount of maintenance may be tolerated, contacts may be worked to 25 or more volt-amperes, but naturally with a reduced life. In the control of large power machinery, greatest reliability of service can be secured by low-duty contacts working through power amplifiers such as pilot exciters or current regulators. In a recent testing laboratory installation, for example, a 37.5-kva motor generator set was successfully governed

Figure 6. Recent commercial application of anticipatory governor to five-horsepower motor generator set

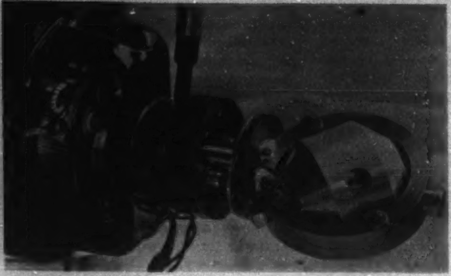

Figure 7. Single-member governor with anticipation

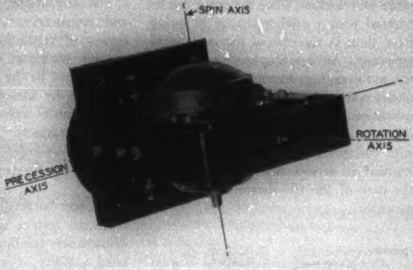

Figure 8. Gyroscopic governor for low-speed control

with a contact-controlled pilot exciter whose output supplied the field power to the motor.

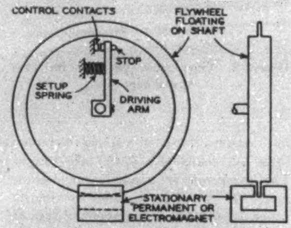
Figure 6 shows a recent application of the two-member governor to a motor generator set for 60-cycle auxiliary power supply. The governor controls the speed of a five horsepower motor through a pilot exciter with an accuracy of two per cent. Smaller machines having little vibration have been governed with accuracies of one per cent or better.

The two-member governor is quite flexible in its adaptability to different operating conditions because both the acceleration and the speed response can be varied independently of each other over a wide range without the necessity of changing such design details as bearing mountings or sizes. It is possible, however, to obtain both speed and acceleration sensing with a single inertia member, although at some sacrifice of application flexibility. A single-member design is shown in figure 7. Its inertia member is a rotor which is pivoted inside a ring frame around an axis inclined at 45 degrees to the axis of rotation of the regulated machine. The rotor is mounted on ball bearings, but is restrained against rotation by a flat torsion spring running through the hollow pivot axis of the rotor. The torsion spring is keyed to the rotor at one end and extends through the ring frame at the other end, where it is fastened to a lever that permits adjustment of the regulated speed by changing the amount of spring setup. The shape of the rotor was calculated to be such that it was in complete dynamic balance to begin with. The requisite amount of unbalance for producing a speed-sensing centrifugal couple could then be introduced either by adding unbalance weights to the rotor or, as is shown in the figure, by removing material by drilling a hole through it.

This design requires but one pair of contacts, but can be used only for one direction of rotation. (A design symmetrically inverted about the motor axis is required for the other direction of rotation.) One contact is stationary on the ring frame, while the other is attached to the movable rotor in such a way that rotation of the rotor about its pivot axis can make and break the control circuit. Angular acceleration of the ring frame will give rise to a rotor inertia torque, which has a component about the pivot axis. Similarly, the centrifugal couple caused by the presence of the hole out of the plane of the ring frame, in an otherwise dynamically balanced rotor, also has a component along the pivot axis. The resultant contact pressure is given by the algebraic sum of the components due to speed and to acceleration.

Another example among the recently developed speed governors is the gyroscopic type, which is shown in figure 8. In the governor types described above the centrifugal force is proportional to the square of the speed. At low speeds large weights are therefore needed to obtain the force required for proper contact operation. Another limitation of the centrifugal governor at low speeds is the magnified influence of gravity disturbances. For example, any mass revolving at a radius of one inch will have a gravity component equal to its centrifugal force at 185 rpm. At low speeds of say 100 rpm or less, it would therefore be practically impossible to obtain any regulation with directly-connected centrifugal governors because of the large weights required and a gravity effect that would be difficult to balance out due to the presence of friction torques. The gyroscopic governor was developed to permit speed regulation in this low speed range with direct coupling to the regulated machine. This is also a contact type of regulator but develops its speed-responsive contact force by means of a gyroscopic torque. The gyroscope is a small single-phase motor of suitable moment of inertia which is mounted with its axis of spin at right angles to the axis of rotation and is supported by ball bearings on its precession axis which is at right angles to both the axis of spin and the axis of machine rotation as shown in figure 8. The precession of the gyroscope is restrained by a loaded spring which holds the contacts open or closed, depending on the control circuit, in the same manner as do the springs used in the centrifugal types. The torque available to overcome this spring is given by the product of the spin inertia of the gyroscope rotor times the spin velocity of the gyroscope times the rotational speed of the regulated machine. From this it is apparent that, although the regulated speed may be low, it is possible to obtain a large precessional torque by making the spin momentum of the gyroscope sufficiently large. Different regulated velocities may be obtained either by changing the precession-spring force or by using a variable-speed motor to control the gyroscope spin velocity.

In comparing the operation of the gyroscopic governor with that of the centrifugal type, it will be noted that the force at the contacts of the former is directly proportional to the regulated speed, while in the latter it is proportional to the square of the speed. The centrifugal governor without anticipation will, therefore, function for either direction of rotation, while it is necessary to provide an additional contact or to reverse the direction of spin if the gyroscopic governor is to regulate for both directions of rotation. The linear speed response of the gyroscopic governor is particularly desirable in applications covering a wide range of velocities, since the range can be covered with a smaller change in spring force than in the case of the centrifugal governor. Antihunting may be added to the gyroscopic governor by making one of the control contacts responsive to acceleration. This may be done by mounting the contact on a mass which revolves with the governor, but which is free to respond to acceleration, as described in the case of the two-member centrifugal governor.



CONTROL CONTACTS
FLYWHEEL FLOATING ON SHAFT
STOP
SETUP SPRING
DRIVING ARM
STATIONARY PERMANENT OR ELECTROMAGNET

Figure 9. Energy-loss type of governor

A fourth type of governor, shown schematically in figure 9, functions by means of speed-responsive forces other than inertia forces. In this, the energy-loss type, the speed-sensitive element consists of a rotating member, such as a flywheel, whose rotation is opposed by forces varying suitably with speed. These forces may originate in eddy-current drag, viscous friction between the rotating member and a fluid, or as a result of imparting kinetic energy to a fluid, as in a centrifugal or axial flow pump. Electromagnetic forces opposing the flywheel rotation may be developed by means of a permanent-magnet field, for example, traversing the rim of the flywheel as shown in figure 9. The flywheel floats on the driving shaft and is driven through an arm rigidly attached to the shaft. The arm carries a contact and is movable through the clearance between a stop and another contact mounted on the flywheel. The speed about which the regulation takes place is determined by the setup in the spring between the arm and the flywheel and by the magnitude of the field traversing the flywheel rim. The latter fact makes it possible to adjust the regulated speed while the machine is rotating simply by changing the position of the magnet relative to the flywheel. The torque for accelerating the flywheel is supplied through the same contact that takes the driving reaction of the forces opposing the flywheel rotation, thus providing a stabilizing acceleration response.

The advantages of design simplicity and compactness together with the accuracy of regulation possible with the contact governors described above can be extended to the field of prime-mover governing by means of electrically operated throttle valves controlled by the governor contacts.

Criteria for System Stability

In order to predict the behavior of a regulated system which is subjected to disturbances tending to change the regulated quantity, it is sufficient in the case of a linear system to determine the transient following a disturbance. The response of a linear system to any disturbance is then completely defined by whether the transient is aperiodic, oscillatory, or self-oscillatory with effectively negative damping. Since the permissible deviations in the regulated quantity are generally small, any system may be considered to be characterized by a linear differential equation in the regulated range and analyzed in this way for stability.

In the case of speed regulators, the system frequency and the amount of positive or negative damping present may thus be obtained from the equilibrium equation between the corrective torques and the opposing torques, due regard being given to their phase relations as affected by the presence of time delays. In the subsequent analysis the effect of load is neglected since it usually does not affect the dynamic characteristics of the system. Even in cases where the load is a function of the speed, the allowable speed deviations are too small to change the load torque appreciably. During correction, therefore, the corrective torques work principally against the inertia of the system in re-establishing the required speed value.

A corrective torque proportional to deviations in angular velocity and to angular acceleration may be expressed as:

$$\begin{aligned}\text{Torque} &= r\Omega + Ip\Omega \\ &= r\Omega\left(1 + \frac{I}{r}p\right) \\ &= r\Omega(1 + T_a p) \qquad (1)\end{aligned}$$

where

Ω = deviation from average velocity in radians per second
r = torque per unit deviation in velocity
I = torque per unit acceleration
T_a = time of anticipation, in seconds
p = usual time derivative operator

The quantity r has the dimensions of a mechanical resistance since it opposes changes in velocity. Moreover, numerically it is a measure of what might be termed the "amplification" of the regulator which initiates the corrective action. All other things being equal, the larger the change in force available at the contacts for a given deviation in speed, the larger will be the amplification r.

The factor of proportionality I between the corrective torque and the angular acceleration has the dimensions of an inertia and has been indicated as such. The symbol I, as used in this sense, does not, however, represent any specific mass inertia in the system, but merely a dimensionally equivalent quantity which may be produced purely electrically, just as may r.

The ratio of I to r has the dimension of time and has been denoted as the time of anticipation T_a. Since both $r\Omega$ and $Ip\Omega$ are caused to appear by virtue of the action of the governor contacts, which contacts function because of contact forces, the time of anticipation may be expressed in terms of governor design constants as the ratio of the change in contact force per unit acceleration to the change in contact force per unit change in regulated velocity, without reference to the circuit producing $r\Omega$ and $Ip\Omega$. That is

F_{Ω_0} = centrifugal force on contact at the regulated speed Ω_0,
F_α = contact force due to an angular acceleration α,

then

$$T_a = \frac{\dfrac{dF_\alpha}{d\alpha}}{\dfrac{dF_{\Omega_0}}{d\Omega_0}} \qquad (1a)$$

For example, in the centrifugal governors described previously,

$$F_\alpha = \frac{I_g\alpha}{h_1}$$

in which

I_g = effective governor flywheel inertia
h_1 = moment arm of contact on which F_α acts
α = angular acceleration

Also,

$$F_{\Omega_0} = mh_2\Omega_0^2$$

where m and h_2 are the effective governor mass and radial distance producing the contact force due to speed and therefore,

$$\frac{dF_\alpha}{d\alpha} = \frac{I_g}{h_1}; \quad \frac{dF_{\Omega_0}}{d\Omega_0} = 2mh_2\Omega_0$$

and

$$T_a = \frac{I_g}{2mh_1h_2\Omega_0} \qquad (1b)$$

A physical insight into the meaning of the anticipation time thus calculated may be gotten by noting that, for the case in which the regulated machine and attached governor are subjected to a suddenly applied constant angular acceleration α, the change in contact force due to the resulting change in speed will become equal to the acceleration contact force only T_a seconds *after* the instant of appearance of α. In other words, the acceleration response in the governor produces a contact force, calling for a correction, T_a seconds *before* a similar call would be produced if the change in contact pressure were only due to a change in speed.

The corrective torque given by equation 1 is subject to time delays in any actual system. In the case of electrically produced torques, these delays are caused by the inductance of field and armature windings which prevents the instantaneous building up of current upon application of voltage. For example, if we consider a simple circuit consisting of an inductance L in series with a resistance R, it is well known that for the case of a suddenly applied voltage E to such a circuit the current will ultimately reach a value E/R, rising to within $1/\epsilon$ of this value in a time $T = L/R$. The differential equation governing the rise in current is:

$$Ri + Lpi = E$$

where p is again the time derivative operator.

Solving for the current,

$$i = \frac{E}{R + Lp}$$

This may be written as

$$i = \frac{E}{R(1 + Tp)} \qquad (2)$$

Although equation 2 is written for current, it also represents the character of a torque as influenced by a time delay. It will be noted that the delay time T appears in the denominator of equation 2, in contrast to T_a in equation 1, which appears in the numerator and indicates anticipation. A quantity $(1 + Tp)$ in a differential equation term may therefore be thought of as an operator having mathematically the same character as the quantity $a + jb$ in the theory of a-c vectors, indicating a phase advance or anticipation when appearing in the numerator and a phase lag or delay when appearing in the denominator.

It can be shown in this manner that when the corrective torque is subject both to an anticipation time T_a and to time delays T_1, T_2, T_3, etc., the correct representation for it is

$$\text{Torque} = \frac{r\Omega(1 + T_a p)}{(1 + T_1 p)(1 + T_2 p)(1 + T_3 p)} \cdots \qquad (3)$$

The multiplicative grouping of time delays in the denominator of (3) can be simply demonstrated, for example, for the governor-controlled Ward-Leonard system of figure 10*a*. This system comprises two time delays which act in series so to speak, one delay arising from the inductance of the generator field and the other from the combined effective inductance of the generator armature and the controlled-motor armature. The incremental current and voltage relations of the circuit are as follows:

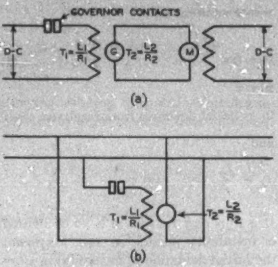


Figure 10. Systems with two time delays

(*a*)—Ward-Leonard system

(*b*)—Shunt motor with field control

$$i_1 = \frac{e_1}{R_1 + pL_1}$$

where

e_1 = variation in generator field voltage E
R_1 = resistance of generator field
L_1 = inductance of generator field

The variation e_2 in the generated voltage due to i_1 is

$$e_2 = Ki_1 = R_2 i_2 + L_2 p i_2$$

where

i_2 = current variation in armature of controlled motor
L_2 = combined inductance of generator and controlled-motor armatures
R_2 = combined resistance of generator and motor armatures

Hence,

$$\frac{i_2(R_2 + pL_2)}{K} = \frac{e_1}{R_1 + pL_1}$$

Or,

$$i_2 = \frac{Ke_1}{(R_1 + pL_1)(R_2 + pL_2)} = \frac{Ce_1}{(1 + T_1 p)(1 + T_2 p)} \qquad (4)$$

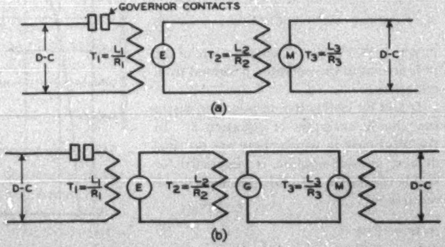
in which

$$T_1 = \frac{L_1}{R_1}; \quad T_2 = \frac{L_2}{R_2}$$

Since the field of the regulated motor is constant, equation 4 also represents the character of the motor torque as influenced by the electrical time delays of the system.

Another system with two delays is shown in figure 10*b*, comprising a shunt motor with field control by means of a contact governor in the motor field circuit. One delay is due to the field inductance while the other arises from armature inductance. The latter is due to the fact that at a given speed a small change in the motor field produces a small change in torque which is at first exactly opposite the required corrective torque, and the corrective torque only attains its required value when the armature IR drop, which is prevented from changing instantaneously by the armature inductance becomes equal to the new difference between the applied voltage and the changed back electromotive force due to the change in field.

When the field of a governed motor is energized by a pilot exciter whose field is regulated by the motor governor, as shown in figure 11*a*, the corrective torque controlling the motor speed is retarded in phase by three time delays. This is



Figures 11a and b. Systems with three time delays

(*a*)—Field control with pilot exciter

(*b*)—Ward-Leonard system with pilot exciter true also for the case of a Ward-Leonard system with a pilot exciter or other current regulator, as shown in figure 11*b*. The circuit of figure 11*c* is also a system with three time delays, but differs from the others in that the pilot exciter is arranged to permit across-the-line starting of the motor. When the circuit is energized, the main motor field is fully excited, and regulation is then effected by the pilot exciter which is mounted on the main motor shaft and produces a counter electromotive force which reduces the motor field to the proper value to establish the desired speed. The currents and voltages in a system comprising any number of such cascaded machines can be shown to be so related, in a manner analogous to the case of the two-delay Ward-Leonard system, as to produce a corrective torque which is mathematically expressed by a multiplicative denominator grouping of the several time delays involved.

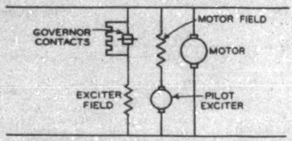


Figure 11c. Governor-controlled motor with pilot exciter for across-line starting

The speed-governing torque of equation 3 will generally be opposed by the inertia torque due to the rotational inertia of the moving system, the effect of load being neglected as explained previously. The differential equation governing the free motion of the regulated system is therefore:

$$I_r p\Omega = -\frac{r(1+T_a p)\Omega}{(1+T_1 p)(1+T_2 p)(1+T_3 p)}\cdots \tag{5}$$

in which I_r = moment of inertia about rotational axis. Its solution is

$$\Omega = C_1\epsilon^{P_1 t} + C_2\epsilon^{P_2 t} + C_3\epsilon^{P_3 t} + \ldots \tag{6}$$

in which $P_1, P_2, P_3 \ldots$ are the roots of the polynomial in the operator p formed from equation 5.

It will be instructive to consider first a few simple examples of equation 5. In the ideal case in which there are no time delays, no anticipation is necessary for stable regulation. In this case equation 5 reduces to

$$I_r p\Omega = -r\Omega \tag{7}$$

whose solution is

$$\Omega = \Omega_1\epsilon^{-\frac{r}{I_r}t} = \quad {}^{-\frac{t}{T_0}} \tag{8}$$

where

Ω_1 = initial deviation from regulated speed

and

$$T_0 = \frac{I_r}{r}$$

It is apparent that there is no oscillation or instability possible in such a system: the initial deviation Ω_1 in speed dies away at a rate determined by the ratio of the rotational inertia to the regulator amplification. As was to be expected, the higher the amplification and the smaller the system inertia, the more quickly will the regulated speed be re-established following a transient disturbance.

When the corrective torque is subject to one time delay T_1, as in a series motor, or a shunt motor with armature control, the equation of regulation becomes:

$$T_0 p\Omega = -\frac{\Omega}{1+T_1 p} \tag{9}$$

Its solution is given, in accordance with equation 6, by the roots of the derived quadratic in p:

$$p^2 + \frac{1}{T_1}p + \frac{1}{T_0 T_1} = 0 \tag{10}$$

This represents a damped free oscillation with a vibration frequency of

$$f = \frac{1}{2\pi}\sqrt{\frac{1}{T_0 T_1} - \frac{1}{4T_1^2}} \text{ cycles per second} \tag{10a}$$

and a fractional decay per cycle of

$$D = 1 - \epsilon^{-\pi\sqrt{\frac{T_0}{T_1}}} \tag{10b}$$

(A fractional decay is defined as shown in figure 12.)

There is, therefore, no instability possible in a linear system characterized by equation 9. With a large delay T_1 or a small T_0, however, the amplitude decay may be so small that in an actual system of this type large free oscillations may be continually excited by transient variations in either the load torque or the driving torque.

By adding an anticipatory response to the governor controlling the corrective torques, the conditions of equation 9 are changed to:

$$T_0 p\Omega = -\frac{\Omega(1+T_a p)}{1+T_1 p} \tag{11}$$

The power of anticipation to neutralize the action of time delays may be well illustrated here by observing that when T_a is made equal to the delay time T_1 the factor $(1 + T_a p)$ just cancels the denominator and equation 11 reduces to equation 7, thus making the system highly damped and nonoscillatory.

In systems with two time delays, like those of figure 10, the equation of motion leads to a third-degree equation in p, with the result that not only is oscillation possible, but the system may also become unstable due to effectively negative damping. The general equation for this case with anticipation is:

$$I_r p\Omega = -\frac{r(1+T_a p)\Omega}{(1+T_1 p)(1+T_2 p)} \tag{12}$$

giving the following polynomial in p:

$$T_0 T_1 T_2 p^3 + T_0(T_1 + T_2)p^2 + (T_0 + T_a)p + 1 = 0 \tag{13}$$

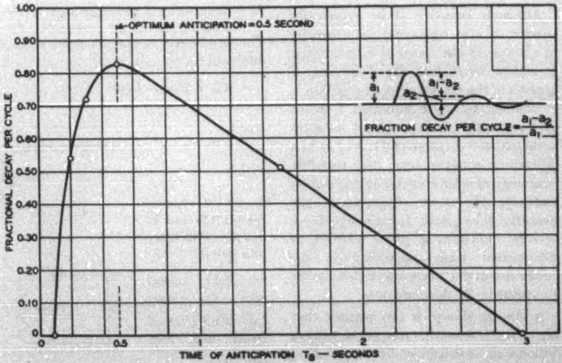

Figure 12. Damping in regulated 37-kva motor generator set

in which $T_0 = I_r/r$ has the dimensions of time.

The roots of (13) will represent a stable solution only if all the coefficients of p are positive and if

$$T_0(T_1 + T_2)(T_0 + T_a) > T_0T_1T_2$$

or

$$T_0 + T_a > \frac{T_1T_2}{T_1 + T_2} \qquad (14)$$

The first condition for stability is obviously satisfied in equation 13. The condition expressed by the inequality (14) forms the basis therefore for the design of the governor and the determination of the system stability limits. T_0 is usually very small when high accuracy is required, hence T_a is the principal stabilizing influence.

It might be supposed by analogy with the case of one time delay discussed previously that the best conditions of regulation would be realized by making the anticipation time cancel one of the two delays, preferably the longer one. That is not the case, however, as can be seen by analyzing (13) for the criteria for optimum damping of the system. When T_0 is small compared to the other time constants and T_a is comparable to T_1 and T_2, then the cubic (13) may be factored approximately into:

$$(T_ap + 1)\left[\frac{T_0T_1T_2}{T_a}p^2 + \frac{T_0}{T_a}\left(T_1 + T_2 - \frac{T_1T_2}{T_a}\right)p + 1\right] = 0 \qquad (15)$$

The quadratic factor of the form $ap^2 + bp + c = 0$, represents the damped oscillation

$$\Omega = \epsilon^{-\Delta t}(A \cos 2\pi ft + B \sin 2\pi ft)$$

in which

$$\Delta = \frac{b}{2a}$$

$$f = \frac{1}{2\pi}\sqrt{\frac{c}{a} - \frac{b^2}{4a^2}} \qquad (16)$$

The fractional decay per cycle is

$$D = 1 - \epsilon^{-\frac{\Delta}{f}}$$

and this is a maximum when Δ/f is a maximum. From (16):

$$\frac{\Delta}{f} = \frac{2\pi}{\sqrt{\frac{4ac}{b^2} - 1}} \qquad (17)$$

The fractional decay is therefore a maximum when $4ac/b^2$ is a minimum. Therefore, the optimum anticipation time for maximum damping is the time that will make $b^2/4ac$ a maximum. This is obtained from

$$\frac{\partial}{\partial T_a}\left(\frac{b^2}{4ac}\right) = 0 \qquad (18)$$

Applying relation (18) to the quadratic (15), the best anticipation time becomes:

$$T_a = \frac{3T_1T_2}{T_1 + T_2} = \frac{3}{\frac{1}{T_1} + \frac{1}{T_2}} \qquad (19)$$

and the best decay factor is

$$\frac{\Delta}{f} = \frac{2\pi}{\sqrt{\frac{9T_aT_1T_2}{T_0(T_1 + T_2)^2} - 1}} = \frac{2\pi}{\sqrt{27\frac{(T_1T_2)^2}{T_0(T_1 + T_2)^3} - 1}} \qquad (20)$$

In order that

$$D \geqq 1 - \frac{1}{\epsilon}, \quad \frac{\Delta}{f} \geqq 1$$

must be true.
Hence,

$$\frac{27(T_1T_2)^2}{T_0(T_1 + T_2)^3} - 1 \leqq 4\pi^2 \leqq 39.4$$

from which

$$T_0 \geqq \frac{0.67(T_1T_2)^2}{(T_1 + T_2)^3} \qquad (20a)$$

For cases where $T_2 \ll T_1$, the best anticipation time is, from (19):

$$T_a = 3T_2 \qquad (20b)$$

and

$$T_0 \geqq 0.67\frac{T_2^2}{T_1} \text{ for } D \geqq 1 - \frac{1}{\epsilon} \qquad (20c)$$

When $T_1 = T_2$, the best anticipation time is

$$T_a = \frac{3}{2}T_2 \qquad (20d)$$

and

$$T_0 \geqq 0.084T_2 \text{ for } D \geqq 1 - \frac{1}{\epsilon} \qquad (20e)$$

By way of comparison, we note that when the anticipation time is made equal to the longer of the two delays, say T_1, the cancellation of $(1 + T_1p)$ in equation 12 reduces it to the form of equation 9. In order then that $D \geqq 1 - 1/\epsilon$, from (10*b*) it is apparent that

$$T_0 \geqq \frac{T_2}{\pi^2} \qquad (20f)$$

The amplification r given by the equality (20*f*) is thus seen to be inferior to the amplification with the optimum T_a, as given by (20*c*) and (20*e*).

Systems with three time delays form an important class since they include the highly useful circuits of figure 11; namely, the field-controlled motor with a pilot exciter and the Ward-Leonard system with the generator field energized by a governor-controlled pilot exciter. Mathematically equivalent conditions exist when the pilot exciter in each case is replaced by any other current regulator having one time delay. The differential equation of free motion for these cases is given by:

$$I_rp\Omega = \frac{-r\Omega(1 + T_ap)}{(1 + T_1p)(1 + T_2p)(1 + T_3p)} \qquad (21)$$

This leads to the following polynomial in p:

$$T_0T_1T_2T_3p^4 + [T_0T_1T_2 + T_0T_3(T_1 + T_2)]p^3 + T_0(T_1 + T_2 + T_3)p^2 + (T_0 + T_a)p + 1 = 0 \qquad (22)$$

A sufficient condition for stability is in this case:

$$T_0(T_0 + T_a)(T_1 + T_2 + T_3)[T_1T_2 + T_3(T_1 + T_2)] > (T_0 + T_a)^2T_1T_2T_3 + T_0[T_1T_2 + T_3(T_1 + T_2)]^2 \qquad (23)$$

The appearance of T_a^2 in the right-hand member of (23) indicates that there is a limit to the anticipation time beyond which the system will be unstable, for by making T_a large enough the inequality (23) will obviously be not satisfied. To determine this limit it is necessary to solve (23) for T_a at the limiting condition of equality. To simplify the expressions, let

$$T_1 = aT_0; \quad T_2 = bT_0; \quad T_3 = cT_0; \quad T_a = dT_0 \qquad (23a)$$

The equality derived from (23) then becomes

$$(1 + d)^2abc - (1 + d)(a + b + c)[ab + c(a + b)] + [ab + c(a + b)]^2 = 0 \qquad (24)$$

This is a quadratic in $(1 + d)$, whose solution is:

$$1 + d = \frac{[ab + c(a + b)]}{2abc}\left[(a + b + c \pm \sqrt{(a + b + c)^2 - 4abc})\right] \qquad (25)$$

A further restriction on the regulating system appears in equation 25. It is apparent that d will be real only when the quantity under the radical is positive. This requires that

$$4abc \leqq (a + b + c)^2 \qquad (26)$$

Or, substituting in (26) the values of a, b, c from (23*a*):

$$T_0 \geqq \frac{4T_1T_2T_3}{(T_1 + T_2 + T_3)^2} \qquad (26a)$$

Hence, the amplification

$$r \leqq \frac{I_r(T_1 + T_2 + T_3)^2}{4T_1T_2T_3} \qquad (26b)$$

Thus, in a three-time-delay system, the time of anticipation and the allowable amplification are both limited. When equations 26 are satisfied, the anticipation time for stability is confined between the limits given by equation 25. That is,

$$1 + d > \frac{[ab + c(a + b)]}{2abc}\left[a + b + c - \sqrt{(a + b + c)^2 - 4abc}\right] \quad (27a)$$

and

$$1 + d < \frac{[ab + c(a + b)]}{2abc}\left[a + b + c + \sqrt{(a + b + c)^2 - 4abc}\right] \quad (27b)$$

The difference between (27*a*) and (27*b*) lies in the sign before the radical.

Since instability occurs at both the limits set by (27*a*) and (27*b*), it is to be expected that a best value of $d\ [=T_a/T_0]$, for which the system damping is maximum, exists between these extremes. It is difficult to find a general expression for this best T_a, however, as that involves factoring the fourth-degree equation 22. In a specific case, when numerical constants are available, the optimum anticipation time can be readily obtained from a point-by-point solution of (22). This was done in a recent application involving the regulation of a 37.5-kva motor generator set through field control by means of a governor-regulated pilot exciter. The pertinent machine constants in this case were:

Exciter field time constant = 0.05 second = T_1
Motor armature time constant = 0.2 second = T_2
Motor field = 0.8 second = T_3
Regulated speed = 1,800 rpm
Full-load motor torque = 146 pounds-feet
Total inertia of rotating parts = 55.4 pounds-inches-seconds² = I_r

Assuming that a regulation accuracy is required which will not permit over two per cent speed change for a variation in load from no load to full load, the necessary amplification becomes:

$$r = \frac{146 \times 12}{0.02 \times 2\pi \times \dfrac{1{,}800}{60}} = 465 \text{ pounds-inches per radian per second}$$

Hence

$$T_0 = \frac{I_r}{r} = \frac{55.4}{465} = 0.12 \text{ second}$$

and

$$a = \frac{T_1}{T_0} = \frac{0.05}{0.12} = 0.417$$

$$b = \frac{T_2}{T_0} = \frac{0.2}{0.12} = 1.67$$

$$c = \frac{T_3}{T_0} = \frac{0.8}{0.12} = 6.67$$

As a first check on the system stability, we note that criterion (26*a*) is satisfied, since

$$0.12 > \frac{4 \times 0.05 \times 0.2 \times 0.8}{(0.05 + 0.2 + 0.8)^2}$$

or

$$0.12 > 0.029$$

Substituting *a*, *b*, and *c* into the relations (27*a*) and (27*b*), we next determine the limits of anticipation time. From (27*a*) we get

$$1 + d < 25.8$$

$$d < 24.8 \left[d = \frac{T_a}{T_0}\right]$$

Hence

$$T_a < 0.12 \times 24.8 = 2.98 \text{ seconds}$$

Similarly, from (27*b*):

$$T_a > 0.094 \text{ second}$$

A point-by-point solution of equation 22 for values of T_a between the limits defined above gives the results shown in figure 12. The system damping, as expressed by the fractional decay per cycle becomes a maximum for an anticipation time of one-half second and is equal to zero for the limiting values of anticipation found above.

Characteristics of Restricted Ionization and Its Relation to Voids in Insulating Materials

C. L. DAWES
FELLOW AIEE

P. H. HUMPHRIES
MEMBER AIEE

THE phenomena accompanying the formation of corona about cylindrical conductors and the laws governing such corona formation have been under investigation for a number of years, and the relations of such corona loss to voltage gradient, pressure, temperature, and the geometry of the system are now quite completely rationalized. Corona or ionization also occurs in restricted spaces, such as the voids which frequently are formed in dielectrics during their fabrication, and this corona formation has important effects on the behavior of such dielectrics. An example of such restricted corona formation is to be found in high-voltage impregnated-paper cables[1,2,3] within which occluded-gas spaces occur. Although the characteristics presented in this paper are for gaps longer than those ordinarily occurring in cables,[4,5,6] data obtained with cables show that the characteristics differ only quantitatively. The effect of such gaseous films on the deterioration of the insulation is well known. A knowledge of the characteristics of restricted ionization has made it possible to separate the solid-dielectric and the ionization losses in cables.[2,3]

In the investigations described in this paper, a large number of measurements of restricted ionization under various conditions of voltage, pressure, and frequency have been made. From the data so obtained attempt has been made to establish certain rational laws for restricted ionization. The phenomena accompanying restricted ionization are far more complicated than those accompanying corona about a cylindrical conductor and the laws therefore cannot always be reduced to simple forms. Also, this investigation contributes to the knowledge of the phenomena which, in general, accompany the ionization spark-over of gases.

Electric Phenomena in Gases With Uniform Field

When an increasing voltage is applied between two parallel, flat electrodes, with gas as the intervening medium, an arc discharge will occur when the sparking gradient is exceeded. Many complex phenomena occur, however, between the initial application of voltage and the ultimate arc discharge. Although these phenomena have been studied by a number of investigators, there is still considerable doubt as to the exact nature of the phenomena which take place during some parts of the breakdown cycle. This is due to the fact that shortly after cumulative ionization by collision begins, the impedance characteristic of the gas becomes unstable and arc discharge follows almost instantly. The unstable impedance characteristic, combined with the rapidity of the arc discharge, makes it very difficult to determine experimentally the volt-ampere characteristic over a considerable part of the cycle. However, by combining the experimental results of a number of investigators, together with their conclusions, it becomes possible to sketch an approximate volt-ampere characteristic, indicating in a general way the nature of the phenomena, from the initial application of voltage to the ultimate arc discharge.

In any normal gas space there is usually a limited supply of free ions. When a small voltage gradient is applied between parallel, flat electrodes, some of these free ions are withdrawn from the field resulting in a very small current. At some definite gradient, the current becomes practically constant and remains so until the gradient becomes sufficient to produce ionization by collision. When the action becomes cumulative, the current increases to an indefinitely large value with but slight increase in the voltage gradient. This characteristic of the gas has been investigated at low pressures by Townsend, and figure 1 is the same as figure 45, page 266, in his book.[7]

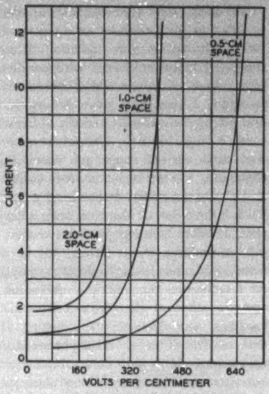

Figure 1. Volt-ampere characteristic at 4.13 millimeters pressure (Townsend)

There is very little in the literature which shows the complete volt-ampere characteristic of a gas. Engel and Steenbeck,[8] however, do present schematically a nearly complete characteristic (figure 86, page 120),[8] in part theoretical, and this is, in slightly modified form, shown in figure 2.

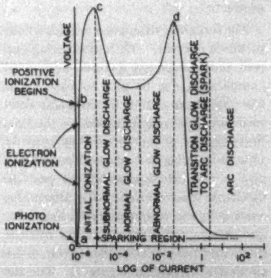

Figure 2. Complete characteristic of self-sustained gas discharge (approximate)

Paper 39-109, recommended by the AIEE technical program committee, and presented at the AIEE North Eastern District meeting, Springfield, Mass., May 3–5, 1939. Manuscript submitted June 22, 1938; made available for preprinting April 12, 1939.

C. L. Dawes is associate professor of electrical engineering and P. H. Humphries is former research associate in the Graduate School of Engineering, Harvard University, Cambridge, Mass.

This research was made possible by a grant from the William F. Milton Fund which is available at Harvard University for research. The authors are indebted to A. F. Daniel and W. M. Goodhue who contributed some of the experimental data presented in the paper; to Doctor J. T. Littleton of the Corning Glass Company and to the American Optical Company for their co-operation in supplying and grinding the glass disks; to Doctor J. D. Cobine and Dean Emeritus Harry E. Clifford of the Graduate School of Engineering, Harvard University, for their helpful suggestions in the preparation of the paper.

[1] For all numbered references, see list at end of paper.

Although this characteristic applies to tubes at low pressures, in the general form it should not differ materially from the characteristic obtained with parallel plates and at much higher pressures. In figure 2 current is given as abscissa and voltage as ordinate, and the abscissa scale is logarithmic. The phenomena over each current range are shown in the figure. In the region *oa*, only casual and photoions exist. Ionization by collision is first due to electrons only, since their mobility is much greater than that of the positive ions. Hence, between *a* and *b* ionization is due to electrons only. At *b* ionization by positive ions begins and the slope of the characteristic diminishes, the characteristic reaching a first maximum at *c*. The phenomena which occur from glow to arc discharge are often considered as taking place in the sparking region and this is indicated in figure 2. The authors know of no data showing definitely which of the two maxima, *c* or *d*, is the greater. However, the results obtained by the authors, combined with sparking experiments of Townsend, indicate that *c* is the greater.

It would follow from figure 2 that for an arc to occur between parallel, flat electrodes, the voltage should not only be sufficiently high to initiate ionization by collision, but must exceed the maximum voltage represented by the maximum *c* or that represented by the second maximum *d*, whichever of these is the greater.

As has already been pointed out, the reason that the characteristic of figure 2 has not been completely explored experimentally is the fact that the discharge becomes unstable and cannot be sustained for a sufficient time to permit measurement. There have been attempts to overcome this difficulty by having in series with the discharge a disk made of high-resistance ceramic products.[9]

The foregoing discussion applies wholly to direct current. With alternating current the phenomena become even more complicated due in part to time lag in the ionization and to the irregular wave forms of the current caused by the nonlinear nature of the circuit (see figure 5). Due to time lag in ionization by collision and in the deionization of the gas, the discharge characteristic with alternating current in the region of initial ionization and subnormal glow discharge will undoubtedly have a hysteresis effect similar to that indicated in figure 3. The decreasing values of current require less voltage than the increasing values.

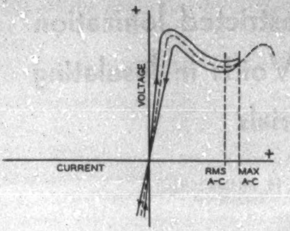

Figure 3. Portion of a-c discharge characteristic

(Also see figure 111, page 165, reference 8).

Slepian,[10] in his studies of arc discharge and reignition, shows a similar effect in the regions of arc discharge. Due to the high initial ionization occurring with arcs under a-c conditions, the discharge does not go through the initial ionization condition and a maximum such as *c*, figure 2, does not occur. With electrodes similar in geometry and of the same material, the positive and negative characteristics are similar in both the arc and the glow discharges. With electrodes of different material or of different geometry, the positive and negative characteristics may be dissymmetrical.

In our research, the left-hand portion of figure 2, to just beyond the maximum *c* has been investigated with alternating current. The discharge has been stabilized by means of a disk of glass, the electrical characteristics of which have been determined. The disk is in series with the corona discharge.

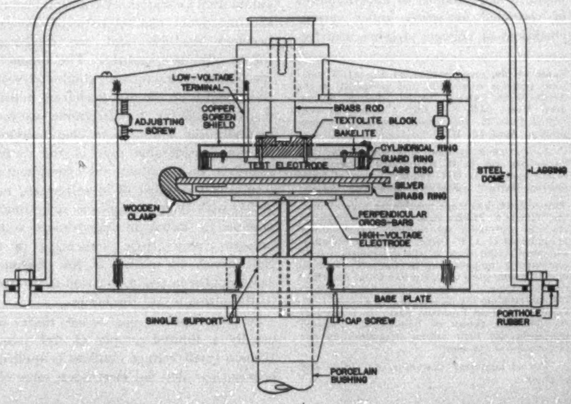
Apparatus and Procedure

The apparatus assembly is shown in figure 4. The test electrode was practically at ground potential. The electrode to which the glass disk is attached is the high-voltage electrode. The original apparatus differed slightly from that shown in figure 4, for, as the work progressed, minor improvements were made. The activating and mechanical action of the discharge is so great that even chromium plating on brass and steel electrodes was chipped in a relatively short time. Ultimately, it was found that only disks of hard chrome steel resisted indefinitely the destructive effects of the corona. The disks were accurately ground, lapped, and polished, although frequent polishing is necessary.

The diameter of this disk is 16.5 centimeters (6.5 inches) making the area 214 square centimeters (33.2 square inches). It is surrounded by an annular guard 1.27 centimeters (0.5 inch) radial width with a 0.238-centimeter ($^{3}/_{32}$-inch) space intervening. The thickness of the disk is 0.476 centimeter ($^{3}/_{16}$ inch). An outside cylindrical ring 0.317 centimeter ($^{1}/_{8}$ inch) thick and 3.17 centimeters (1.25 inches) axial length forms part of the guard.

The disk is mounted on a vertical shaft 2.54 centimeters (1 inch) diameter

Figure 4. Ionization test apparatus



by means of a block of Textolite, and the shaft is free to move vertically in a close-fitting bearing. The length of gap is first determined by a micrometer and then verified by the capacitance which can be accurately measured and calculated. The two values ordinarily check each other within three per cent. The low-voltage electrode is shielded on top by a copper screen. Thermocouples are mounted on the disk for determining the temperature.

The diameter of the glass disk is 24.1 centimeters (9.5 inches) and 0.530 centimeter (208.5 mils) thick. It is silvered to within approximately 1.27 centimeters (0.5 inch) of the edge.

The disks are of a special low-dielectric-loss and high-permittivity glass supplied by the Corning Glass Company. The surfaces of the disks were ground accurately, the disk was silvered on both sides, and the electrical characteristics were measured over a frequency range of from 25 to 75 cycles and a temperature range of from 20 degrees to 100 degrees centigrade. The characteristics are independent of voltage. The silver on one surface was then removed. The silver on the other surface made contact with the high-voltage electrode and the nonsilvered surface was adjacent to the gap. The disk acts as a series ballast, which stabilizes the corona discharge.

The assembly is mounted on a tripod structure, figure 4. The structure is in turn mounted on a base of boiler plate 1.59 centimeters ($^{5}/_{8}$ inch) thick, by a single central support so that deflections of the base plate due to changes in pressure do not change the air-gap. A dome thoroughly heat-lagged and with a small glass window for observation purposes is set over the apparatus and is bolted to the base plate making the apparatus air tight. A continuous stream of air passes through the apparatus during measurements. Unless this air is thoroughly dried, erratic results are obtained, and products resulting from the chemical action of the corona on the moisture are found in the gap. The air is dried by passing it through activated alumina. There is a resistor unit for controlling the temperature and there is also a small electric fan for circulating and agitating the air.

Measurements were made with a mutual-inductance, high-voltage bridge, in the high-voltage laboratories of the Graduate School of Engineering of Harvard University.[11] The voltage wave was sinusoidal, as shown in figure 5.

All necessary shields and guards were used and each was balanced to the potential of its shield. A tuned vibrating galvanometer was used as the detector. Since such a galvanometer responds to the fundamental frequency only, the characteristics measured were in terms of fundamental frequency. Due to the nonlinear characteristics of the gas, the percentage of harmonics in the current wave is large and harmonics of very high frequency occur. In figure 5 is shown a typical oscillogram of voltage and current waves taken at 11.5 kv and with a gap of 0.159 centimeter.

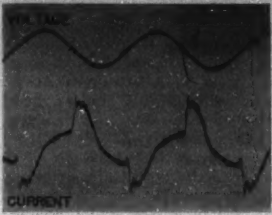


Figure 5. Oscillogram for gap of 0.159 centimeter—11,500 volts—pressure 76 centimeters

The branch of the bridge circuit consisting of the standard air capacitor and resistance (R_1) in series is linear so that the current in this circuit is sinusoidal. Since harmonic currents cannot contribute power with respect to the fundamental voltage, the power measured by the bridge is that corresponding to the fundamental voltage across the bridge and the fundamental current to the specimen.

An amplifier was used in the detector circuit of the bridge. It has been shown[12] that nonlinearity in an amplifier or other circuit element may cause two or more harmonic electromotive forces in the input to yield a fundamental component in the output and thus introduce error into the measurements. To eliminate this error, the amplifier is made essentially linear and the galvanometer circuit is provided with three low-pass filters which cut off at 45, 67, and 100 cycles.

Although the results submitted are in terms of the fundamental, the voltage across the gap itself cannot be exactly sinusoidal. This is due to the fact that this voltage is the difference between the sinusoidal voltage impressed across the glass disk and gap in series and the nonsinusoidal impedance voltage drop in the glass disk. To correct for this factor would involve great complication and no attempt is made to do so. Moreover, the conduct of our experiments corresponds with the conditions usually met in practice. Also, our results agree so closely with those obtained by other investigators, whose methods did not involve restricted ionization, that we feel that omitting the correction did not have any substantial effect in the results. Moreover the harmonics in the current wave for the most part are of very high frequency so that the impedance drop in the glass disk, due to them, is small.

From each bridge measurement, the total impedance of the glass and the gas space or gap in series was determined. By subtracting the known impedance of the glass disk from the total impedance, the impedance of the gap under the particular condition is determined. The several electrical characteristics of the gap, such as voltage gradient, power factor, power loss, can then be computed.

Measurements were made with gap lengths varying from 0.08 to 0.4 centimeters and at pressures of from 20 to 100 centimeters of mercury. Although measurements have been made at different frequencies, the results submitted in this paper are confined to 60 cycles. As the pressure is decreased, the maximum current density which can be obtained also decreases, because of the correspondingly reduced arc-over voltage of the apparatus. A very large number of tests have been made, but owing to space limitations only typical ones are given in this paper.

Voltage Gradient—Current Density

When the gap is ionized, a large space charge exists within it. Positive ions are moving toward the negative boundary of the gap and negative ions are moving toward the positive boundary of the gap. Also some recombinations are taking place. The space charge must have some effect on the distribution of gradient within the gap. This effect is complex and no attempt is made to correct for it. The values of gradient given, therefore, are the average for the gap.

In figure 6 are shown average voltage-gradient–current-density characteristics at different pressures for air-gaps of two different magnitudes, the average thickness of one gap being 0.180 centimeter and of the other 0.382 centimeter. Until ionization begins, the characteristics for all gaps are linear and identical, the gradient being merely that for a centimeter-cube constant-capacitance, parallel-plate air capacitor. Although these characteristics were obtained at widely different times and under different conditions, the initial linear portions of all the characteristics lie in the same straight line and the coincidence of the experimental points with the linear characteristic is surprisingly close. This indicates, we believe, that the precision of the measurements is good.

Ionization begins at the critical gradient G_o, beyond which the rate of voltage-increase diminishes rapidly, the gradient reaches a maximum at G_m and with further increase in current density the gradient diminishes. G_o lies at the intersection of the linear and the curved portion of the characteristics and can be critically determined since it corresponds to the beginning of an energy component of the gradient. The range of the characteristics shown in figure 6 lies in the initial-ionization and subnormal glow-discharge regions of figure 2 and the maxima in figure 6 correspond to the maximum shown at *c* in figure 2.

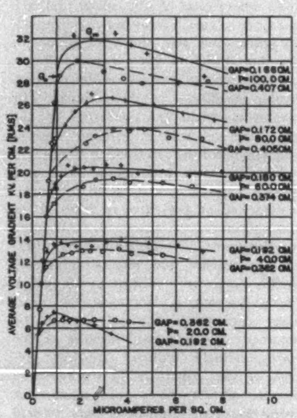

Figure 6. Voltage-gradient, current-density characteristics at several pressures

In figure 7 are shown three characteristics giving the relations, for very short gaps, of average voltage gradient to current density at three different pressures. The average gap length is 0.0871 centimeter. Comparing the initial linear portions of the characteristics of figures 6 and 7 with the initial portion of figure 2, the ionization current is completely masked by the displacement current. After ionization begins, however, the power factor rises rapidly and reaches values of nearly unity (figure 16). Hence, a short time after the ionization voltage is reached, the energy current becomes strongly predominating and apart from some variations due to time lag in the ionization, the characteristics with alternating current should not differ very greatly from those with direct current.

The characteristics in figures 6 and 7 show certain definite properties of ionized gaps. The maximum gradient G_m, and G_o become greater with decreasing length of gap. This is well illustrated in figure 7 in which the characteristic for the shortest gap is shown, and is in accordance with Townsend's equation for gap spark-over (equation 1). Both G_o and G_m diminish with the pressure and with decrease in pressure the difference between G_m and G_o also diminishes.

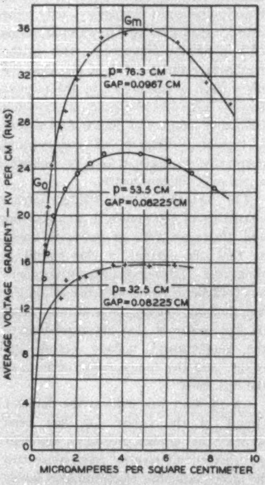

Figure 7. Voltage-gradient, current-density characteristics for short gap

From the foregoing it follows that the sparking voltage-gradient for gases between electrodes is not constant, but at constant pressure and temperature, is a function of the distance *S* between electrodes. The relation of the sparking gradient to *S* has been determined by several investigators but their results are not in close agreement. This is undoubtedly due in large measure to the different conditions under which the investigations were conducted. Townsend[7] (also see 13, page 116), experimenting at atmospheric pressure with gaps of the order of $^1/_{16}$ inch (0.16 centimeter) has found that the sparking gradient *G* may be expressed by the following equation:

$$G = G_o + \frac{1.35}{S} = 30 + \frac{1.35}{S} \text{ kv per centimeter} \qquad (1)$$

where G_o, = 30 kv per centimeter direct current, is the approximate initial breakdown or critical gradient of air at atmospheric pressure, and *S* is the length of the gap in centimeters. Other investigators give equations of the same general character as (1). S. Whitehead[13] (diagram II, page 42) gives, in the form of a graph, the combined results of a large number of investigators. In accordance with Paschen's law, the abscissas are given as the product of pressure *P* and spark length *S*, the pressure being in millimeters of mercury and the spark length in centimeters. The sparking voltage *V*, for the region represented by the gaps investigated by the authors (diagram II, page 42), is

$$V = 5 + 0.0353PS \text{ kv} \qquad (2)$$

Dividing by *S* and taking a pressure of 760 millimeters,

$$\frac{V}{S} = G = 26.8 + \frac{5}{S} \text{ kv per centimeter} \qquad (3)$$

the equation of which is similar in form to (1) but is only in rough numerical agreement with it. Slepian, in figure 58, reference 14, shows an experimental sparking-potential curve which is in quite close agreement with equation 1 for the magnitude of gaps investigated by the authors.

In figure 6 the critical gradient G_o at 80 centimeters pressure for the 0.172-centimeter gap is 22 kv per centimeter root-mean-square or 31 kv per centimeter maximum; the initial ionization for the 0.405-centimeter gap is 20 kv per centimeter root-mean-square or 28.3 kv per centimeter maximum. These values are very close to the generally accepted value of G_o and to the value given by Townsend in (1). In figure 7 the critical gradient for the 0.0967-centimeter gap at 76.3-centimeter pressure is 22.5 kv per centimeter root-mean-square or 31.9 kv per centimeter maximum, which is higher than the value for the two longer gaps. This, however, is rational since the critical gradient increases with decrease in length of gap.

Equations, such as (1) and (3), for the sparking voltage gradient are the result of experiment and are essentially empirical. So far as the authors are aware, no satisfactory physical basis for this form of equation has been given. This is particularly true for the second term which is proportional to $1/S$. The authors believe that the characteristics of figures 6 and 7 offer a rational explanation of this term. Sparking cannot occur when the gradient is less than the value G_m. This is due to the fact that between G_o and G_m the slope of the characteristic is positive and the impedance of the gap during this interval is stable. However, after the gradient reaches the value G_m, represented by the maximum of the characteristic, the slope of the characteristic becomes negative, the impedance of the gap becomes unstable, and cumulative ionization and transition from initial ionization to glow or arc discharge follow depending on circuit constants. Obviously sparking cannot occur at the gradient G_o but only when the maximum gradient G_m is reached. Therefore, the second term in (1) and (3) must represent the difference between the sparking gradient, G_m, and the critical gradient G_o.

Also, the increasing difference between G_m and G_o with decreasing length of gap, as shown in figures 6 and 7, explains why the second term in the equations 1 and 3 for sparking gradient is proportional to $1/S$.

There are several theories to account for the fact that spark-over does not occur at the gradient G_o but rather at the gradient G_m. Until the gradient G_m is reached, ionization by collision, primarily by electrons, has not become cumulative, so that sparking cannot occur until G_m is reached. Cumulative ionization does not occur until additional processes such as collision ionization by positive ions, electron emission by positive-ion bombardment of the cathode, ionization and photoelectric emission by ultraviolet radiation, and also the action of metastable atoms, become appreciable. The effectiveness of these processes varies according to experimental conditions.[14,15]

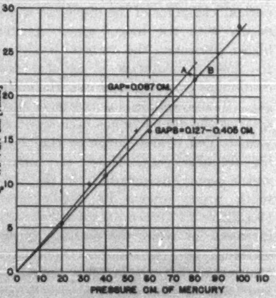

Figure 8. Critical-gradient and pressure

Effect of Pressure

Paschen's law states that the sparking potential is a function of the product of the density of the gas and the spark length. This law holds over a considerable range. With parallel fixed electrodes the sparking potential should be proportional to the pressure.

In figure 8 are two characteristics showing the relation of critical gradient G_o to pressure. The upper characteristic A is plotted from the values of G_o in figure 7. The data for the lower characteristics B, were obtained in part from figure 6 and also from similar characteristics for gaps with varying lengths. The critical gradients for the 0.087-centimeter gap are greater than for the longer gaps. However, it was found that for gaps of 0.17-centimeter and greater, the critical gradient becomes substantially independent of gap length. Both characteristics are linear showing that the critical gradient is proportional to the absolute pressure.

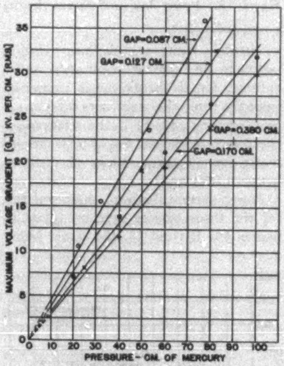

Figure 9. Maximum voltage-gradient and pressure

The equations of characteristics A and B are respectively:

(A) $G_o = 0.297\,p$ kv per centimeter (root-mean-square) (4)

(B) $G_o = 0.27\,p$ kv per centimeter (root-mean-square) (5)

where p is given in centimeters of mercury.

In figure 9 is shown the relation of maximum voltage gradient G_m to pressure for four different gap lengths, 0.087, 0.127, 0.17, and 0.38 centimeter. In each case the characteristic is linear showing that the maximum gradient in kilovolts per centimeter (root-mean-square) also is proportional to the absolute pressure.

$$(S=0.08\text{ cm})\qquad G_m=0.46\,p \qquad (6)$$

$$(S=0.127\text{ cm})\qquad G_m=0.39\,p \qquad (7)$$

$$(S=0.17\text{ cm})\qquad G_m=0.33\,p \qquad (8)$$

$$(S=0.38\text{ cm})\qquad G_m=0.30\,p \qquad (9)$$

In figure 10 the maximum gradients, corresponding to 76 centimeters pressure and the slopes of the characteristics taken from figure 9, are plotted as functions of gap length. Figure 10 shows that the maximum gradient G_m increases with decreasing length of gap. This is in accordance with theory (reference 13, diagram VI, page 44) and also in accordance with equations 1 and 3. Also for gap lengths of 0.3 centimeter and greater, the slopes of the G_m-p characteristic and the value of G_m become essentially constant.

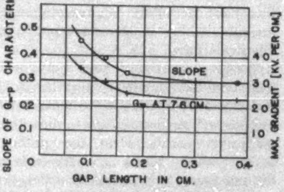

Figure 10. Slope of G_m-p characteristic and maximum gradient versus gap length

Using the characteristics of figures 8 and 9, the equations of the sparking gradient G $(=G_m)$ in terms of maximum gradient (root-mean-square $\sqrt{2}$) are for each gap length in kilovolts per centimeter (maximum):

$$(S=0.08\text{ cm})\qquad G=\left(0.44+\frac{0.0215}{S}\right)p \qquad (10)$$

$$(S=0.127\text{ cm})\qquad G=\left(0.39+\frac{0.0195}{S}\right)p \qquad (11)$$

$$(S=0.17\text{ cm})\qquad G=\left(0.39+\frac{0.0144}{S}\right)p \qquad (12)$$

$$(S=0.38\text{ cm})\qquad G=\left(0.39+\frac{0.0161}{S}\right)p \qquad (13)$$

At 76 centimeters pressure, equations 10, 11, 12, and 13 become respectively:

$$G=33.5+\frac{1.63}{S} \tag{14}$$

$$G=28.8+\frac{1.48}{S} \tag{15}$$

$$G=28.8+\frac{1.1}{S} \tag{16}$$

$$G=28.8+\frac{1.22}{S} \tag{17}$$

These equations are in reasonably close agreement with those of other investigators.

The first terms of equations 11, 12, and 13 are the same. In all four equations, (10–13), the second term depends on the length S of the sparking distance; and because of the linearity of the characteristics of figures 8 and 9, the sparking voltage is proportional to pressure, which is in accordance with Paschen's Law.

Sparking equations 1 and 3 of Townsend and S. Whitehead, together with their close correlation with equations 6 to 17 as well as figures 6 and 7, show that spark-over occurs when the gradient G_m is reached. Since G_m corresponds to the maximum c in figure 2, under the conditions of these tests spark-over must occur when the gradient given by c is reached.

Power–Current-Density Characteristics

When power is plotted as a function of current density, the relation invariably has been found to be essentially linear, particularly at atmospheric pressure. When the complicated phenomena which must be taking place in the ionized gas space, particularly under a-c conditions, are considered, it seems remarkable that the relation should be so simple. However, this linear relation seems to be inherent, even with direct current, for if the power is computed from the three characteristics determined by Townsend, figure 1, the relations of the power to current are also essentially linear for all three values of distance between electrodes.

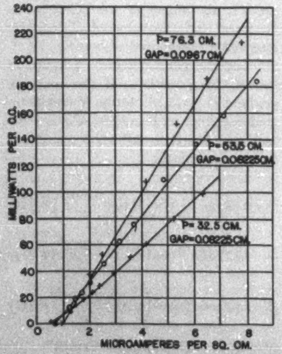

Figure 11. Power loss and current density

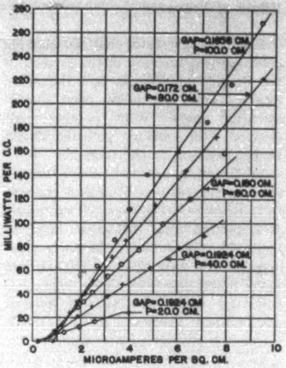

Figure 12. Power loss and current density

Power-current-density characteristics for the three typical gaps are given in figures 11, 12, and 13, the power being given in milliwatts per cubic centimeter. In figure 11 are given the characteristics for the average shortest gap (0.087 centimeter average), in figure 12 the characteristics for the average intermediate gap (0.18 centimeter average) and in figure 13 the characteristics for the average longest gap (0.382 centimeter average). The characteristics at the different pressures are essentially linear. They also show that the power loss per cubic centimeter increases with the pressure. The relation is shown in figure 14 which gives the power loss characteristics at constant current density of six microamperes per square centimeter for the three typical gaps, as functions of pressure. The characteristics are concaved slightly downward and if extrapolated apparently go through the origin. Obviously the power loss at zero pressure should be zero. The characteristics are of the exponential type, the exponents being slightly less than unity. The equation for each characteristic is given in the figure.

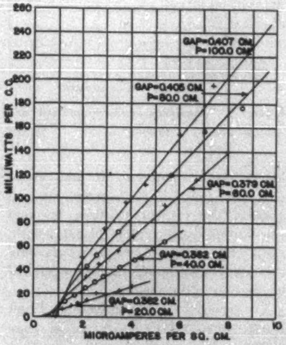

Figure 13. Power loss and current density

In figure 13, which gives the power loss for the longest gap of 0.382 centimeter (average), with the higher pressures and at the lower current densities the characteristics break slightly downward as they approach the axis of abscissas. This is due to the intermittent character of the discharge which occurs with the longer gaps. At the higher pressures, the current density is too low to maintain a uniform and continuous glow discharge over the entire gap. The resulting intermittent character of the discharge has been observed visually and is also shown by the sharp high-frequency pulsations of current which occur intermittently in the sawtooth waves shown by oscillograms. (See figure 5.) When the current density increases, or when the pressure is decreased, the intermittent discharge changes to the steady glow discharge and the power-current-density characteristics become linear throughout as

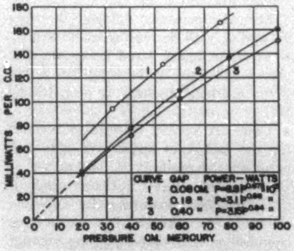

Figure 14. Gap loss and pressure, current density six microamperes per square centimeter

shown at the higher current densities and at the lower pressures of 40 and 20 centimeters, figure 13.

The normal power-current characteristics must intersect one another at the low values of current density and power. This is due to the fact that the current density at which ionization begins, diminishes with the pressure, whereas the slopes of the characteristics increase with the pressure. These intersections are shown clearly in figures 11, 12, and 13.

Since the power–current-density equations are essentially linear, they may be expressed by the general form of equation,

$P = m(I - I_o)$ watts per cubic centimeter **(18)**

where P is the power in watts per cubic centimeter, m the slope in watts per ampere per square centimeter, I the current density in amperes per square centimeter, and I_o the ionizing current density in amperes per square centimeter.

The ionizing current density is proportional to the pressure. No attempt was made to make precise determinations of the critical values.

Equation 18 holds only when $I > I_o$ and for the linear portions of the characteristics for the pressures of 100, 80, and 60 centimeters, figure 13. It is interesting to note that for a given gap the slopes of the characteristics in figures 11, 12, and 13 are linear functions of the pressure. This is illustrated in figure 15 which gives the slopes for these different average gap lengths. These characteristics are linear but do not go through the origin. They show that the rate of power increase is a linear function of the pressure.

Power Factor

Below ionization, the power factor of the gap is zero, there being no conduction except the very small amount due to random ions. After ionization by collision begins, a pronounced power loss occurs, and the power factor increases rapidly from its zero value and at moderate values of current density reaches values as high as from 0.8 to nearly unity. Characteristics at different pressures for the gaps having average length of 0.18 centimeter are shown in figure 16. The power factor increases almost immediately to values ranging from 0.6 to 0.8, after which the rate of increase diminishes. We find that for any given pressure the longer the gap the greater the power factor. Also the lower the pressure the greater the power factor. The power-factor characteristics at the lower pressures rise more rapidly and attain values approaching unity at much lower current densities than do those for the higher pressures.

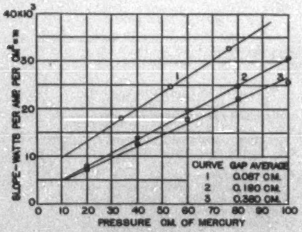

Figure 15. Relation of rate of power increase to pressure

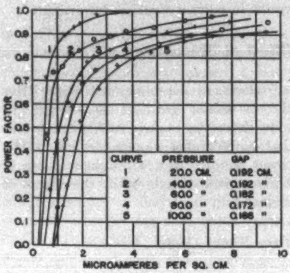

Figure 16. Power-factor characteristics

The general equation for the power factor characteristic is given by the power equation (18) divided by the product of voltage gradient and current density. That is

$$\text{P.F.} = \frac{m(I - I_o)}{EI} \qquad (19)$$

for $I > I_o$.

Also the power factor is a function of both pressure and gap length. Although empirical relations among these parameters can be determined, they would be far from simple and thus would add little to the understanding of the fundamental physical phenomena.

The rapid increase in power factor may be accounted for also by the very rapid increase in the series dielectric constant with current density (see figure 17) and the accompanying increasing power loss (figures 11, 12, 13).

As stated earlier in the paper, the fact that the power factor increases so rapidly to values approaching unity undoubtedly accounts for the fact that the characteristics of the gap with alternating current are of substantially the same character as for those with direct current.

Dielectric Constant

Under given conditions, an imperfect capacitor may be replaced in an electric circuit by either a perfect capacitance in series with a resistance, each of appropriate value, or by a perfect capacitance in parallel with a resistance or a conductance, each of appropriate value.[16] It is often convenient, particularly in circuit computations, to substitute an equivalent circuit for the imperfect capacitor.

Characteristics showing the variations in the equivalent parallel capacitance and resistance with change in current density may indicate the physical changes which are taking place.

The space charge within the ionized gap shortens the dielectric lines and accordingly increases the capacitance. The oscillations of the ions due to the alternating field reduce the dielectric constant.[17] The effect of the oscillation is noticeable only at very high frequencies, and not appreciable at power frequencies. The increase in capacitance may be considered as due to an increase in the dielectric constant of the ionized medium between the capacitor electrodes. The capacitor is changed from a perfect one to an imperfect one by the losses in the gap due to ionization.

In figure 17 are shown the values of series dielectric constant for the 0.18-

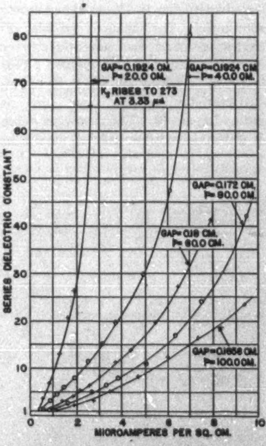

Figure 17. Series dielectric constant and current density

centimeter (average) gap at pressures of 20, 40, 60, 80, and 100 centimeters of mercury. These characteristics are not very different from those of the 0.382-centimeter (average) gap. The values of dielectric constant for a given value of current, however, are much less with the 0.08-centimeter gap. It is to be noted that with diminishing values of pressure there is an extremely rapid rise in the value of dielectric constant. For example, at 20 centimeters pressure the value at 3.33 microamperes per square centimeter is 273. At atmospheric pressure the dielectric constant has a value of about 40 at a current density of 9 microamperes per square centimeter.

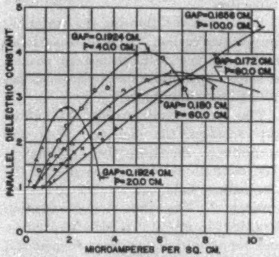

Figure 18. Parallel dielectric constant and current density

In an equivalent parallel circuit the value of capacitance necessary to replace a given imperfect capacitor becomes much smaller than with the series equivalent circuit, after the losses have become substantial. The values of parallel dielectric constant are accordingly very much less than the series values. This is shown in figure 18, which gives the characteristics for the same gaps as those of figure 17. The maximum value of dielectric constant reached occurs at 100 centimeters pressure and is equal to only 4.5. The characteristics of figure 18 are typical of a large number which have been obtained. It is to be noted that the characteristic of the gap at 100 centimeters pressure is nearly linear. As the pressure diminishes the characteristics become concaved downward, reach maximum values and with further increase in current density drop rapidly.

Effect of Frequency

Preliminary experiments indicate that the maximum gradient is affected in some degree by change in frequency and that considerable change occurs in the power factor. In a subsequent paper it is planned to show in detail the effects of frequency.

Very Short Gaps

In cable insulation a large proportion of the gaps or air films are of the order of 2.5 to 5 mils (0.0064 to 0.013 centimeter) thickness, whereas the shortest gap on which these tests were conducted is 0.07 centimeter or five to ten times the thickness existing in cables. The rate of change of characteristic increases rapidly with decrease in gap length, as shown in figure 10. With decrease in length of gap, the irregularities of the electrodes have much greater proportional effect. It is planned, however, to combine a more sensitive bridge with small precise specimens and to use a more precise micrometer adjustment of the gap with the object of obtaining data for these very thin gaps.

Corona Discharge on Rubber-Insulated Cables

E. B. PAINE

H. A. BROWN
MEMBER AIEE

Introduction

Nature of Investigation and General Method

When rubber-insulated cables operate at higher than 1,500 volts potential, conditions may be favorable to the production of corona discharge over all or a portion of the outer surface of the insulation, or its braid covering. The cable may be on an inner metal conduit surface, or lie on a grounded flat metal surface, all of these conditions being favorable to surface corona at sufficiently high voltages. Corona discharge is known to be objectionable because of the chemical effect of the actinic ozone produced, and because of inductive and radiation effects, notably interference with radio reception.

The purpose of this investigation was twofold: First, it was desired to learn how cables of different designs, ratings, insulation characteristics, etc., compared as to corona behavior when an operating condition is imposed which tends to produce corona at nominal voltages. Second, it was desired to learn what effect, if any, corona discharge may have on the power factor of the insulation under the test conditions.

It was decided to test each piece for corona discharge and power factor behavior as it lay on a flat metal plate, with the ends of the test piece upturned to prevent flashover at the ends. Each test piece was 34 to 36 inches long. As potential between the conductor and this contact surface is increased, a value will be reached where corona discharges will begin within a more or less limited or concentrated region, close to the point where the insulation surface is in contact, or near contact with the metallic plate. Several ozone determinations were made when disruptive discharge phenomena were electrically detected, with means described in this paper. Some test pieces possessed very stiff, heavy wire, and braid having a rough, irregular surface, so that it was very difficult to attain firm contact at every point. In fact, the contact for such test pieces was not uniform, as would often be the case in practice. This condition will be termed *erratic contact*, and for such cases corona discharge will start at several points, and at the lowest voltage. When the voltage is further increased a value will be then reached where visible corona discharge more or less suddenly extends from the curving away points of contact to a continuously visible state of corona along the entire length of the cable including regions of firm contact as well. Power-factor measurements were made with voltage applied between the conductor and metal contact plate with and without corona, and with unbraided samples. The measured power factors would apply in practice to lengths of line actually in contact with the metal plate.

The conclusions are itemized below. They show that corona discharge may well occur at or near normal operating voltages under conditions liable to be obtained in actual use, and in addition to the previously assumed effects of ozone production, power factor may be affected.

Tests were made on an insufficient number of cables shielded with semiconducting materials or metallic tapes to justify any conclusions at this time regarding the effect of such shielding on corona behavior.

Conclusions

1. The commercial two-kv cables with ozone-resisting rubber insulation both with braid and without braid and its saturant are in general properly rated as to voltage from the corona starting point of view. The five-kv cables are close to the nominal rating. The 12-kv and 14-kv cables which were tested appear to be overrated, since corona discharge occurs below the normal operating voltage.

2. Corona starting voltages increase with the thickness of the rubber insulation for all samples tested with braid removed and for those without braid. This is not strictly true when braid is present. Corona starting voltage was found to decrease from 17 to 30 per cent for an increase of about 70 per cent in the specific inductive capacity of the insulation rubber.

3. For most cables, the voltage for fully visible corona along the entire length of the cable resting on the test plate is about 30 per cent higher than the voltage at which corona begins.

4. Ozone is produced in the case of a rubber-insulated cable resting on a metal when and only when the potential difference between the conductor and plate is sufficiently great to cause disturbances in the charging current, which may be measured by the methods described.

5. In some cases of five-kv unbraided cables tested at line voltage, the presence of corona discharge increases the power factor, when measured on a flat metal plate, to several times the value of power factor at the same voltage but with corona suppressed by the application of air pressure. When the cable has a braid covering the power factor is markedly higher than the

power factor without the braid, and the presence of corona discharge has almost negligible effect on the power factor.

6. The method of detecting the presence of corona discharges by the effect of the disturbances caused by corona on the charging current has been found to be highly sensitive and satisfactory.

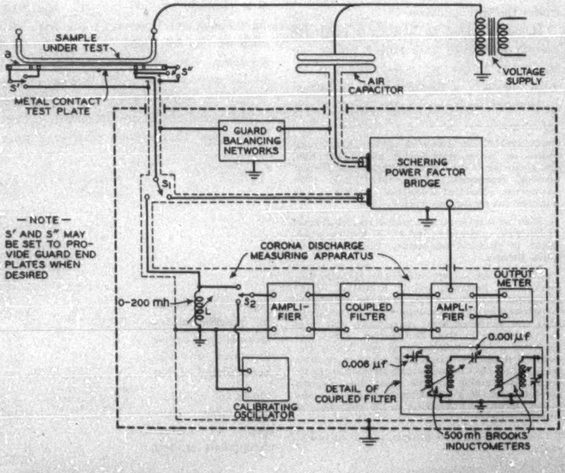
Relation of Ozone Production to Corona Discharge

Quantitative Test for Ozone Production

A quantitative test for the amount of ozone produced was carried out on several representative pieces of cable. It was desired to learn whether or not sufficient ozone was liberated under ordinary operating conditions to be quantitatively measurable. The method of procedure in this determination is indicated by the schematic diagram of figure 1. The test piece is enclosed in a suitable glass tube, having flat glass end plates, cemented in place with beeswax, and provided with holes which allow the conductor of the test sample to protrude at each end, the insulation terminating at the inner surfaces of the end plates. The metal-contact test plate was placed within the glass enclosing tube and tied to the test piece as shown. During the application of sufficient voltage to obtain electrically detectable discharge disturbances for several hours, ozone accumulated within the enclosing tube. Care was taken to allow only thoroughly dry air in the enclosing tube at the start of the test. After removing the voltage, the air and accumulated ozone within the enclosing tube were swept out with dry carbon dioxide and into an absorbing tube containing the chemical absorbing and buffer solutions indicated in figure 1. About 15 minutes is required thoroughly to sweep out the enclosing tube of all traces of ozone. The absorbing solution absorbs the ozone and iodine is liberated, giving the solution a brownish orange color. After this, more sodium acetate solution is added and then a few drops of soluble starch solution, which changes the test solution to a dark blue color. The amount of ozone is then determined by titration, sodium thiosulphate is added drop-wise until the solution becomes clear. The number of grams of ozone liberated is then equal to 0.024 times the cubic centimeters of sodium thiosulphate added.

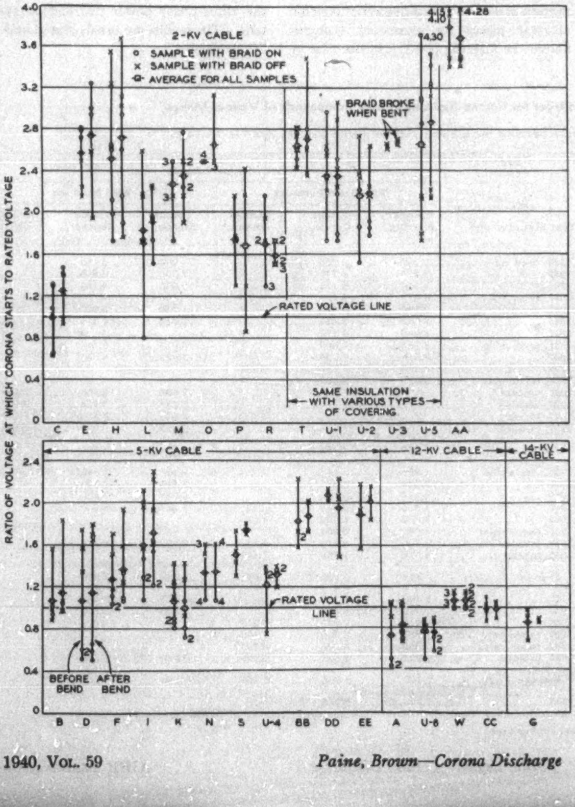
Some typical test data are shown in graph form in figure 2, the amount of ozone produced being compared with the corona discharge intensity and voltage applied. In each case the variation of corona discharge current with voltage is shown. This was determined in a manner described later. It will be noticed that at the voltage for which output-meter indications of corona discharges are obtained, it required more than four hours to obtain a measurable quantity of ozone, and that the ozone produced increased rapidly at voltages above this value. Comparing the graphs on the right-hand side of figure 2, it should be noted that when the special setup of the lower graph is used, in order to remove the curved ends of the test plate to the outside of the glass enclosing tube, measurable ozone was not obtained until the voltage was increased from less than three kilovolts to about five kilovolts. This means that the ozone produced at the critical separation of insulation and test plate where the insulation curves away from the test plate was, of course, not included in the collected ozone, and that ozone could not be collected until the voltage arose to a value which produced corona discharge uniformly along the length of test plate inside the enclosing

Figure 3. Test circuit for rubber-insulated cables



tube and in firm contact with the insulated surface. In this test care was taken to use a test sample which was sufficiently flexible so that it could be held in firm contact with the test plate by being bound thereto with waxed lacing cord. It should be here pointed out that in this latter test setup, detectable discharges were obtained at 2.8 kv, as shown in the upper right-hand graph. The end contact plates shown in this special setup in this figure were connected to ground, but this does not remove the effect of corona discharges at the curving away region from the detecting-recording apparatus. The discharge phenomena in this region disturbs the charging current to the active portion of the test plate connected to the detecting apparatus by capacitance coupling, although to a lesser degree than if the curved end plates, or they might be considered as guard plates, were conductively connected to the active test plate within the enclosing tube.

Figure 4. Relation of corona starting voltage to operating voltage of rubber-insulated cables



Corona Characteristics for Various Types of Rubber-Insulated Cables

Description of Test Equipment and Procedure

The test arrangements for detecting and measuring the corona discharge current are shown in figure 3. This apparatus has been formerly described[1] and has since been slightly modified. The metal-contact test plate is shown with *guard end plates* which can be connected to the active test plate or isolated therefrom and grounded by means of switches S' and S'' as shown. The transfer switch, S_1, connects the test plate to the apparatus for detecting and measuring the discharge phenomena when this switch is closed to the left. This connects the test plate through the series variable air-cored inductance to ground, as shown. Previous investigation work on high-voltage paper-insulated cables[1] showed that the potential drop across this variable inductance at the random damped conglomerate discharge frequencies, which vary from 4,000 to 9,000 cycles, is greatly increased in proportion to the drop across this inductance at the 60-cycle charging-current frequency and harmonics thereof. Therefore, this inductance is the first step in filtering out the potentials due to charging current. Through switch S_2 closed on the upper position potentials across the inductance are carried to a one-stage shielded amplifier employing a type 37 tube and output transformer with a 2,000-ohm secondary, this transformer having a high-fidelity frequency response. A coupled filter system, indicated in the figure, effectively suppresses all remaining 60-cycle charging current and harmonics thereof. This filter system is more fully described in the reference previously made, and is very briefly diagrammed in the detailed insert in figure 3. The Brooks inductometer makes a satisfactory type of astatically wound, variable coupling inductance in this filter system. The filter is followed by a three-stage amplifier, comprising metal tubes of the 6*J*7, 6*C*5, and 6*F*6 types, all resistance coupled, and terminating in an output transformer with a 5,000-ohm secondary. The output meter must be one of flexible range and sensitivity. A multirange milliammeter, reading 0–100 microamperes for its lowest range, is used, and in series with this is connected a type 230 tube with grid tied to plate as a rectifier. The conventional input gain-control potentiometer is incorporated in the main or second amplifier. When discharges occur in the crevices between the insulation surface and the test plate the output meter will give a convenient reading with proper setting of the gain control, then switch S_2 is closed on the lower position and the output voltage of a calibrating oscillator of 5,000 cycles frequency is suitably reduced in amount through a calibrated attenuator until the output meter shows the same reading as was obtained for the corona discharge on the test plate. Knowing the value of the variable inductance and assuming a 5,000-cycle average frequency, the current through this inductance is assumed to be equal to the voltage across the inductance as measured by the calibrating oscillator with its associated output voltmeter and attenuator, divided by the 5,000-cycle reactance of the variable inductance *L*. The use of the coupled filter will suppress any 60-cycle component of corona discharge disturbances that may exist, and the application of the steep wave front and random frequency potentials upon the coupled filter results in a certain amount of regularly damped oscillations in the filter network. In order to eliminate all such effects, it is necessary to provide a resistance-capacitance type of bridge circuit incorporating equal resistance ratio arms and a discharge-free capacitor in order to balance out the 60-cycle charging current almost completely so that discharges may be detected. The authors' previous work with high-voltage cables indicates that the test setup indicated in figure 3 gives comparative corona-discharge current intensities just as accurately as the more cumbersome bridge system, and even in the bridge system a small aperiodic filter must be used to remove the unbalanced 60-cycle residue resulting from in-phase loss component in the charging current in the sample under test. Further investigation indicates no appreciable 60-cycle component of ionization discharge current exists, as it would when the metallic test electrodes are completely separated by air or gas so that ions can drift directly from one electrode to the other, as is the case with the conventional corona tube containing air or other gas. When switch S_1 is closed to the right, a Schering power-factor bridge and its associated guard balancing networks and loss-free air capacitor are put into use to measure power factor.

Each sample of rubber-insulated cable was cut into test pieces three feet long so that when bent upward at the ends, about 30 inches was left in contact with the test plate. The test piece was taped to the test plate so as to insure firm contact, but not sufficiently firm as to cause flattening of the insulation surface. As the voltage was raised, a sensitive telephone-receiver headset was used to detect the point at which discharge disturbances began and the output meter deflection occurred. In the cases of most cables tested, discharge disturbances occur with an abrupt start and increase, so that the audibly detectable corona discharge and a readable output meter deflection coincide. Readings were taken for all test pieces for increasing voltages above the starting point. In the case of each piece tested the point at which the corona discharge quite suddenly becomes visible along the entire length of the insulation surface lying on the test plate was also observed.

Results of Tests for Corona Discharges

The principal object of these tests was to make a study of the starting voltage for corona discharge, and to obtain visible voltage behavior for representative samples of rubber-insulated cables. Figure 4 shows diagrammatically the starting corona voltage for each piece tested, before and after bending the test piece three times around a mandril of five times the cable diameter; with braid on, and braid removed, in the case of braided samples. The point conventions are explained on the graph, and the ordinates are plotted with respect to the rated operating voltage line, assuming that test voltage applying between the conductor and plate is compared with the wye-leg voltage or voltage to neutral in the three-phase power distribution system. The results are briefly stated under "Conclusions."

Tables I and II show results indicated in figure 4, but before bending, and show which cables are braided and which are not, and also show average values for the samples with braid on, and with braid removed. The left-hand curve of figure 5 shows that the corona starting voltage increases with the insulation wall thickness and nearly in direct proportion. For 2-kv cables ($^{3}/_{32}$-inch wall) the operating voltage to neutral is nearly one-third the corona starting voltage, while for 12-kv cables the corona starting point is almost at the rated operating neutral voltage. The right-hand curve of figure 5 shows the variation of corona starting voltage with the specific inductive capacity (dielectric constant) of the rubber insulating material using data on samples tested before bending, and for no braid or braid removed. Many factors, of course, cannot be accounted for, but in general a decrease of roughly 30 per cent in corona starting voltage results for an increase of roughly 70 per cent in specific inductive capacity of the rubber. For the higher-voltage cables the decrease is probably around 17 per cent.

Effect of Corona Discharge on Power Factor

METHODS AND CONDITIONS FOR POWER-FACTOR MEASUREMENT

A number of power factor measurements were made in order to learn whether or not the existence of corona discharge had any considerable effect on power factor. The test setup of figure 3 was used again, and for the power factor data submitted in this paper no grounded guard end plates were used, switches *S′* and *S″* being thrown so as to connect the end plates to the center test-plate section. This was done in order to include the effect of the starting corona discharge at the point or points where the insulation curved away from the test plate. The effect of corona discharge on the contact-plate power factor is most readily obtained by observing the change of power factor upon removal of corona discharge by suitable means. To do this the test piece with its contact plate, from which the latter curved at the two ends, was placed inside an adequately sealed three-inch-diameter Pyrex glass tube having one-eighth-inch wall thickness, and a length of 21 inches. When air pressure of 10 to 15 pounds per square inch was provided by means of a tire pump, the corona discharge was completely eliminated, even though the voltage was sufficiently high to produce the uniformly

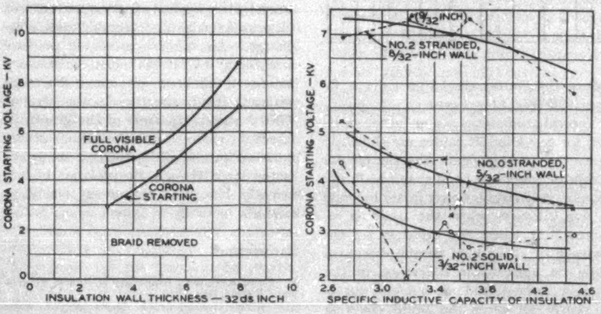

Figure 5. Variation of corona with thickness and specific inductive capacity of insulation rubber

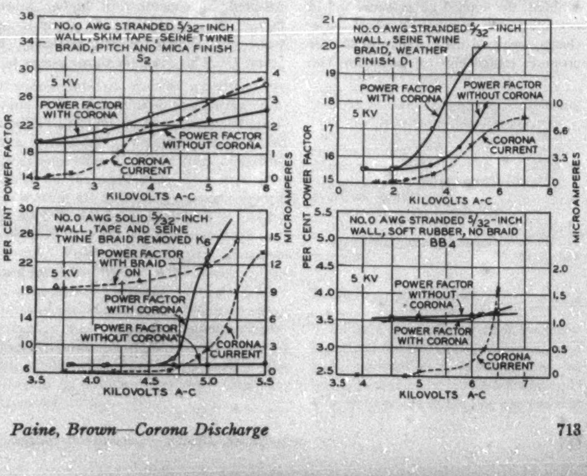
Figure 6. Effect of corona discharge on power factor of rubber-insulated cables tested on metal contact plate



visible corona along the entire length of the test piece lying on the metal plate. In the case of some stranded conductor samples, and some of the samples provided with a tightly woven braid and saturant, the applied air pressure would not completely remove all corona discharge, owing to the inability of the air pressure completely to permeate the space between the braid and the rubber, or between the rubber and the stranded conductor surfaces. In all cases, however, air pressure of 15 pounds per square inch above the atmospheric value would reduce the corona discharge current intensity at least 85 per cent.

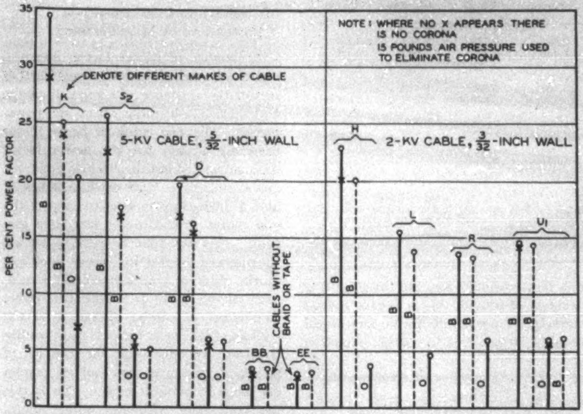


Figure 7. Relation of corona and braid covering to power factor of rubber-insulated cable on flat plate

Values shown are average for three pieces of each make of cable
Solid line—Tested at rated line voltage
Dashed line—Tested at wye leg voltage
O—Power factor at rated voltage
X—Power factor with all or at least 75 per cent of corona discharge removed
B—Tested with braid and other covering on
O—Tested with braid, tape, etc., removed

Typical examples of power-factor variation for five-kilovolt cables are shown in figure 6. In this figure the sample for which the lower left-hand graph is shown, shows a considerable power factor increase at five kilovolts when the braid is removed, but when the braid is on the presence or absence of corona discharge made no appreciable difference in the position of the dotted power-factor curve. In nearly all cases the braid covering resulted in considerably higher power factor. Some results of power-factor tests are shown diagrammatically in figure 7. This diagram shows power factors obtained for both tests at the nominal rated line voltage and for the actual voltage to neutral over which the cables would probably operate in a three-phase system. In all of the samples tested it is quite evident that corona discharge at actual operating voltages has little effect upon the power factor. On some of the vertical lines in the diagram no crosses (indicating power factor with corona discharge removed) appear, these indicating that in these particular instances no corona discharge existed at the testing voltages. One sample shown in this diagram has a power factor of 15 per cent at rated line voltage with braid removed, which was reduced to 7 per cent with applied air pressure. The higher power factor for the test piece with braid covering is due to loss in the braid rather than to any corona discharge, because the power factor remained high when the voltage was sufficiently low so that no corona discharge could be detected, and when existing corona discharge was present, little change in power factor was obtained when applied air pressure removed all or practically all detectable corona discharge. Air or carbon-dioxide pressure was found to be the most satisfactory means of eliminating corona discharge without itself effecting power factor. This is shown by some of the graphs in figure 6 where the application of air pressure produced no change in power factor even though the voltage is sufficiently low that no corona discharge existed.

The Dielectric Strength and Life of Impregnated-Paper Insulation—I

The Influence of the Density of the Paper

J. B. WHITEHEAD
FELLOW AIEE

PAPER as used in the spiral laminated impregnated insulation of high-voltage power cables is available over wide ranges of density and thickness. There result important variations in the ordinary physical properties of the paper such as flexibility, tearing, tensile, and bending strength. Variations in the electrical properties of conductivity, dielectric constant, and breakdown strength also result. The peculiarly severe conditions imposed by the manufacture, transportation, installation, and operation of high-voltage cables have emphasized the importance that full attention be paid to all physical properties of the insulation, especially those relating to permanence of mechanical structure and of high insulating properties. Manufacturers of cables often utilize the several types of variation referred to in designing cable insulation to meet the particular requirements of cables for different types of service.

This paper reports the results of a part of an experimental program of study of the life of impregnated-paper insulation, particularly as related to those changes occasioned by the presence of electric stress, carried out under the auspices of the Engineering Foundation with the sponsorship of the AIEE. The method in view is to make accelerated life and other electrical tests on samples in which the only variable is some one of the physical properties mentioned above. In the present tests this variable has been the density of the paper. Few if any definite data have been presented as to the influence of variations in density on the electrical characteristics of impregnated paper and its performance in service. The results of the present study will be found to be quite definite. From what has been said, however, it will be recognized that the influence of variations in density of the paper must be considered as only one element of the general problem in cable design, and that the influence of a variation in density on other important physical properties must be duly considered in particular cases.

The Papers

Four grades of paper were studied, all by the same manufacturer, from the same basic wood pulp, and all of approximately the same thickness. Table I gives the density of the several grades expressed as specific gravity, and also data as to other properties investigated. The specific gravity was determined by measuring the over-all volume and the weight of 12 pieces of the paper tape piled together under moderate pressure, by similar measurements on three-inch diameter rolls of tape, as delivered, and also as rewrapped under heavy tension. The results of these tests are given in columns 3, 4, 5, and 6 of table I. Those in columns 3, 4, and 6 were made in the research laboratories of the General Cable Corporation through the courtesy of R. W. Atkinson. The figures of column 5 were made in the author's laboratory. The average values in column 7 have been used in plotting the results of the electrical tests. All of the measurements of specific gravity were made under atmospheric conditions. Approximate figures for the amount of moisture contained in the paper under these conditions were obtained from measurements on the same rolls after drying in circulating air at 105 degrees centigrade for approximately 44 hours. The loss by weight in per cent is given in column 8 of table I. Values of the Gurley air resistance furnished by Mr. Atkinson are given in column 9. Columns 10 and 11 give the per cent oil content by volume and by weight in the impregnated paper, as measured after the electrical tests by repeated saturation with ether and repeated distillation in a closed system. (See also figure 4.)

Table I also gives data on grade *E* paper, 0.004 inch thick, as used in an earlier research.[1] The paper was thus about five years old. Certain interesting properties of this paper will be mentioned below.

The Test Specimens

The test specimens were made by lathe, wrapping 16 layers of 0.005 inch (0.0127 centimeter) by 1 inch (2.54 centimeters) paper tapes on smooth brass tubes, with a $33^1/_3$–$66^2/_3$ overlay, and with a butt spacing of the tapes of approximately $^1/_{64}$ inch (0.0397 centimeter). The central or measuring electrode was 42 centimeters long overlapped by and insulated from a foil guard electrode extending up the conical paper reinforcement at each end of the specimen. Further details as to the test specimen will be found in earlier papers.[1,2] Much attention was given to the making of the specimens as nearly alike as possible. They were all given the same drying and impregnation treatment[1] (predrying in moving air at 105 degrees centigrade, evacuation at two millimeters mercury pressure, and 105 degrees centigrade for 24 hours, impregnated with oil degassed at 60 degrees for 24 hours).

Nine identical specimens were constructed from each grade of paper. They were dried and impregnated in groups of three.

The Oil

All specimens were impregnated with a light oil as used for oil-filled cables by American manufacturers. The physical characteristics of the oil are approximately as follows:

Gravity, API/60 degrees	24.8
Flash (degrees Fahrenheit)	320
Fire (degrees Fahrenheit)	360
Saybolt Universal viscosity ÷ 100 degrees Fahrenheit	102
Color N.P.A.	1−
Neutralization number ASTM	Neutral
Pour test (degrees Fahrenheit)	−60
Iodine number	12.4
Sligh oxidation	21.2
Dielectric strength	32.5 kv
Resistivity Race cell/115 degrees centigrade:	
Initial-ohms per centimeter cube	20.0×10^{13}
Aged-ohms per centimeter cube	12.5×10^{13}

Experimental Method

All tests were made on single specimens immersed in the impregnating oil in a bath enclosed in a thermally insulated box with automatic temperature control.[1] The air pressure in the test box was that

of the atmosphere. The temperature for all tests was 40 degrees centigrade.

Life and Breakdown Tests. The accelerated step-up life test started at a voltage to give an average stress of 400 volts per mil on the specimen and the test voltage was increased by 3.12 per cent every four hours, thus giving a geometric increase such as to bring the stress to 700 volts per mil within three days. Under this program the range of life of all specimens tested was from two to four days.

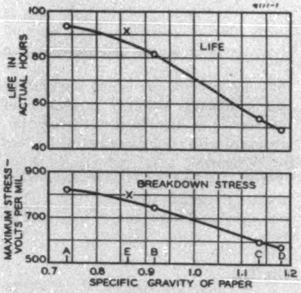

Figure 1. Breakdown strength and life as function of the specific gravity of the paper

Power Factor and Capacitance. Power factor and capacitance were measured on a high-voltage Schering bridge[1] at the beginning of the life test and at 12-hour intervals and over the range 100 to 400 volts per mil.

Conductance. The long-time d-c conductance of the dry paper specimen was measured at 1,500 volts and 105 degrees centigrade before impregnation, and of the impregnated specimen at 60 degrees centigrade immediately following impregnation.

Experimental Results

The results of the accelerated life and breakdown tests on grade *C* paper are given in table II. They are typical of the results on the other grades of paper for which the average values only are given in table II. Using the average values of life and breakdown stress, as taken from table II, and the values of specific gravity and oil content, as given in table I, the results on accelerated life and breakdown and other electrical properties are plotted in figures 1 to 3 inclusive.

The results indicate that with increasing density of the paper, there are marked variations in all electrical quantities as well as in the values of breakdown stress and life.

Breakdown Strength and Life. Both these quantities decrease with increasing paper density over the range studied. (See figure 1.) This similarity of behavior is a necessary consequence of the type of accelerated life test. In the present case it happens that the change in the over-all duration of time (life) is greater than that of voltage. The decrease of dielectric strength and life with increasing density is contrary to the behavior commonly attributed to an increase in density of a homogeneous material and also to the influence often attributed to the use of heavier papers in cable manufacture. Discussion of this result and the probable explanation will be found in a later paragraph.

Power Factor. The values of power factor given in table II are those measured at the beginning of the test at 300 volts per mil. In figure 2 they are plotted as

Table II. Accelerated Life Tests

Specimen	Paper	Stress—Volts Per Mil		Time (Hours)		Power Factor at 300 Volts Per Mil	Dielectric Loss Watts Per Inch Cubed at 300 Volts Per Mil	Capacity (Micromicrofarads) at 300 Volts Per Mil	Conductivity Mhos Per Centimeter $\times 10^{-16}$

function of the density of the paper and it will be seen that there is a uniform rise in power factor with increasing density. Power factor-voltage curves were taken at intervals throughout each life test. They show only slight variations among the various specimens as between the beginning and toward the end of a test. A typical series of power factor-voltage curves is shown in figures 5 and 6, together with typical curves of power factor and temperature variations throughout the course of a test. In a few cases a definite rise in power factor was noted during the last hours of a test. In general, power factor behavior throughout the test indicated constancy of value, little if any internal gaseous ionization, and appreciable rise only in a few cases during the short period in which the specimen was approaching breakdown.

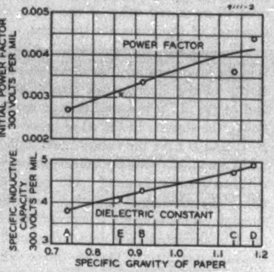

Figure 2. Power factor and dielectric constant as function of the specific gravity of the paper

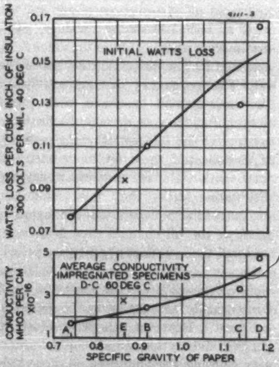

Figure 3. Dielectric loss and long-time d-c conductivity as functions of the specific gravity of the paper

Dielectric Constant. As seen in figure 2 the dielectric constant of the impregnated specimen increases uniformly with increasing density of the paper. On single specimens there was no appreciable change in the value of capacitance either with change of voltage nor over the course of a test.

Dielectric Loss and Conductivity. In figure 3 the dielectric loss at 40 degrees and 300 volts per mil and the long-time d-c conductivity at 60 degrees centigrade, are shown as function of the density of the paper. As indicated, there is a marked increase in both conductivity and loss with increasing paper density.

Oil Content. The oil content of the impregnated paper as per cent by weight and per cent by volume for the different grades of paper is shown in figure 4. It will be seen that the volume of oil absorbed by the several grades of paper follows in linear relation the variation in the density of paper.

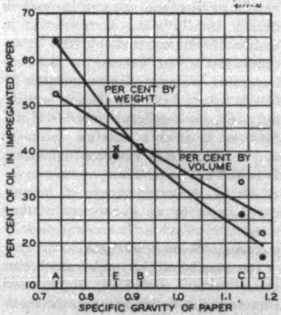

Figure 4. Oil content of impregnated paper by weight and by volume as function of the specific gravity of the paper

Type of Breakdown. All specimens were carefully examined after failure for evidence as to its beginning and cause. In the latter half of the work these studies were greatly facilitated by the use of a thyratron tube, relay, and rapid circuit breaker, for interruption of the primary circuit of the transformer. The combination was actuated by the current to ground from the measuring electrode of the specimen. The operation of this device is so sensitive and rapid that not only is the usual burning attendant upon breakdown almost completely suppressed, but in many cases the circuit is opened before the failure has extended further than two or three layers of paper. By repeated applications or "shots" of voltage, the initial failure can be extended and its path followed. A series of stress values of shots giving repeated interruptions and leading finally to practically complete puncture is as follows: 792, 785, 725, 632 volts per mil; the over-all duration of time for the four shots was about two minutes. In most cases it was found desirable to give the specimen two or three shots to be sure that failure had actually started and to locate definitely its origin.

Failures took place almost invariably under the central electrode, occasionally under the adjacent regions of the guards of equal radial thickness and never, since the early stages, under the conical reinforced ends. All failures have been of definitely radial type.

The clear indication of these studies is that most of the failures begin in the oil channels between successive turns of paper; most often at the central high-voltage electrode, sometimes in the center of the insulation wall, and in a few cases at the outer electrode. In a number of cases in which the specimen was dissected after the first two or three shots, the incipient failure was found to be confined to two or three layers. At one point the oil in a channel would be found to have become black, the blackening extending a short distance either way along the channel and on the edge of the paper. The next stage would be the puncture of one or perhaps two paper layers, but generally reaching the next oil channel on the same radius. Occasionally longitudinal tracking and tree patterns to adjacent channels were noticed, but these extended only a very short distance, probably because of the relatively thin total wall thickness. Evidence of initial blackening in oil spaces was also invariably noticed at the edges of small holes in the central tubular conductor and outer lead foil electrode drilled to facilitate drying and impregnation; however, the failures showed no preference for the edges of these holes.

Altogether the failures seem to be closely similar to those reported by Robinson,[3] with the exception that in our case, the free oil space which is the initial seat of the trouble, may lie in the center of the insulation wall. Robinson finds it to be always next to either the conductor or the sheath.

Open Versus Closed Testing Bath. At the outset the question was raised in the discussion of some of the author's earlier work, as to the reliability of accelerated life tests in a bath open to atmosphere. It was suggested that the absorption of oxygen into the oil of the bath might penetrate to the specimen and thus introduce a cause of instability which would not commonly be present in cable insulation and which it was therefore desirable to exclude in these tests.

In the original choice of the present method of test the adoption of the open bath was based on much independent evidence of the very slow rate at which oxidation of insulating oils takes place at the relatively low temperature of 40 degrees centigrade, and also on the completely enclosed character of the test specimen. These two conditions seemed to indicate that within the period of a few days little or no oxygen could penetrate to the insulation wall of the specimen, and that if it did, its effect on the properties of the insulation would be negligible at the relatively low temperature of the test.

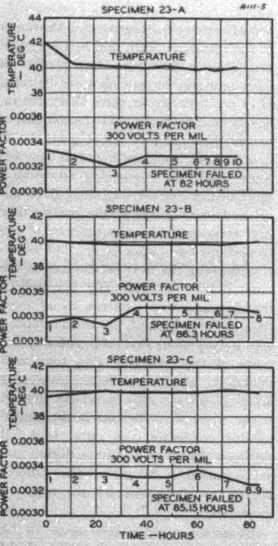

Figure 5. Power factor and temperature variations in the course of a life test

In order to answer this question, and preliminary to the study of paper density, a series of comparative tests was carried out on specimens in open baths and identical specimens completely enclosed in glass. The paper used was a supply of grade *E* (table I) remaining from earlier work. The enclosed specimens were mounted in glass tubes which were open during the process of drying and impregnation, but closed before transfer to the constant temperature test bath.

The results of the tests on eight open and seven closed specimens indicated average values of breakdown voltage closely the same, the difference being well within the experimental error as indicated by the spread of the results on each group. The test in the open bath is much simpler, more convenient, and more rapid, and was therefore continued in the present studies.

Discussion of Results

Breakdown and Life. Under any current theory of the nature of breakdown in insulating materials, an increase in density should be accompanied by an increase in dielectric strength. Most such theories invoke the energy and ionizing power of ions in motion, and since an increase in density usually means a restriction in motion of the ions, it should also be accompanied by an increase in dielectric strength. Widespread experiment is in fact in accord with this theory, particularly for homogeneous materials and for those in which a variation of density may be effected by a variation in pressure. It is well known for example, that an increase in the compactness of impregnated paper by an increase of winding tension or otherwise is accompanied by increase in dielectric strength.

The results of this paper show that under certain conditions, impregnated paper presents an exception to the above mentioned behavior. Variations in density under otherwise uniform conditions may be caused by a variation in the density either of the paper or of the oil, and our present results show that with an increase of the density of the paper by 60 per cent, there results a decrease of dielectric strength of 30 per cent and a life shorter by 47 per cent in our accelerated life tests.

Attention has been called to the evidence that the failures almost invariably begin with the failure of the oil in the interspaces between paper tapes. This suggests at once that an explanation of the results may be found in the increasing dielectric constant of the paper with increasing density, and the consequent transfer of a greater proportion of the over-all stress to the oil. This is, in fact, supported by an approximate computation of the stresses in the oil channels. If we assume that the dielectric constant of the oil is constant at the value 2.15, it is possible, using the over-all measured value of dielectric constant, to compute approximately the dielectric constant of the impregnated paper. Owing to the small volume of free oil space, it is found that the dielectric constant of the impregnated paper itself is about 1.04 times the over-all measured value of the dielectric constant of the complete specimen.

Assuming then that the stress in the oil is in the inverse ratio of the dielectric constants of the impregnated paper itself, and of the oil, it is found that at breakdown, the stresses in the oil of grades *A*, *B*, *C*, and *D* have the values 1,500, 1,550, 1,375, and 1,355 volts per mil respectively, with an average value of 1,445 volts per mil. The maximum deviation from the average value is about 7.3 per cent, which must be considered low under the conditions of experiment. There is thus a definite suggestion over the whole range of papers studied that the specimens fail at approximately the same value of stress in the oil channels.

However, the values of oil stress given above are very high, in fact well above the values at which disruption and breakdown are known to occur in oils. The disruptive strength of carefully purified and dried oils is in the neighborhood of 1,000 volts per mil. Photographic evidence of initial discharges in oil-impregnated paper are reported by Gemant[4] as beginning in the neighborhood of 560 volts per mil. Initial collision ionization causing increased conductivity begins at 300 volts per mil. C. V O. Terwilliger,[5] working in the author's laboratory, has recently reported initial discharges in thin films of carefully dried oil at stresses as low as 60 volts per mil. It may be assumed, therefore, that the computed values of oil stress given above are too high as initial breakdown values. The explanation possibly lies in the value 2.15, assumed for the dielectric constant of the oil. The increase of the conductivity of the impregnated specimen with paper density indicates an increase in the ionic content of the oil (see following section). If, as indicated, these ions move back and forth within the oil channels under the alternating stress, they will accumulate as space-charge layers on the opposite faces of the oil channel each half-cycle, and will thus in effect constitute a polarization in addition to the atomic polarization (corresponding to the value 2.15), and consequently an increase in the dielectric constant. However, an increase of 50 per cent due to this cause would be necessary to bring the computed oil stress values down to the highest disruptive values reviewed above. This is a large increase for the type of cause suggested, but, in view of the very high stresses undoubtedly present, it may be considered as a possible explanation.

Further, it is to be noted also that there is a general trend downward of the values of stress in the oil at breakdown with increasing paper density. This tendency is accentuated if the value for paper *E* (oil stress at breakdown 1,580 volts per mil) is included. Discussion in the following section on conductivity points out that the variation in the conductivity may also be a contributory cause in breakdown, and of such character as to explain the decrease in the critical oil stress with increase of paper density.

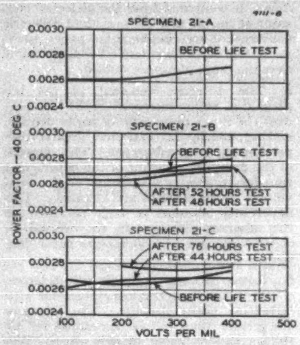

Figure 6. Power factor-voltage relations in the course of a life test

Conductivity. Great interest attaches to the change in value of conductivity with increasing paper density. In figure 3 it is seen that the long-time d-c conductivity at 60 degrees of the impregnated specimen increases about 2.6 times from *A* to *D* paper. Within this same range the mass of paper fiber increases 1.6 times and the mass of oil in the paper decreases to 0.30 times the amount in *A* paper. It is evident, therefore, that the increase in conductivity is greater than can be accounted for by the increase in density.

Two sources of the additional supply of conduction ions suggest themselves. One is soluble material of electrolytic character entering the oil from contact with the paper. The other is residual moisture adsorbed on the paper fibers. The residual conductivity of the dried and evacuated paper measured at 105 degrees centigrade just before impregnation, apparently increases about 2.2 times from paper *A* to paper *D*, that is, over the range of density of the paper. Measurements of the d-c conductivity of different samples of the same dry paper vary widely and cannot be considered as completely reliable indication, but the measurements in question clearly indicated an increase in the average values by the amount mentioned. We may assume that on impregnation some of the adsorbed ions are released by the presence of the oil, entering the latter where they have greater freedom of motion and thereby increase the conductivity of the specimen. With increasing density of the paper, the amounts of both soluble material and adsorbed surface moisture are increased, and thereby the numbers of ions and resulting conductivities as observed.

Some of the original supply of dissolved and adsorbed ions find their way into the oil in the oil channels between the paper tapes. Here they oscillate back and forth under the alternating stress. Their velocity of motion is quite high (of the order 10^{-4} centimeters per second per volt per centimeter)[7] and great enough to cause practically complete passage of all ions present back and forth over the whole thickness of the channel, in one 60-cycle period. It seems possible, therefore, that this large supply of ions in continuous oscillation, either through heating in minute channels, or perhaps better through the formation of space charges and resulting high electric surface intensities, may be the cause of initial breakdown in the oil channels as observed in the tests. Since the conductivities of both dry and impregnated specimens of grade *D* paper are greater than those from grade *A* paper, we should expect under this view a lower oil stress at failure for *D* paper than for *A* paper, as found in the computed values given above.

In this connection attention may be drawn to the properties of the grade *E* paper. As seen in figure 1, both life and breakdown stress of this paper lie above the curves showing the results on papers *A* to *D*. The *E* paper is over five years old, having been stored since some earlier studies. There is also other evidence that the breakdown strength of *E* paper has increased over the storage period. Its particular interest in the present connection is the very low value of the conductivity of the dry paper specimens *E* before impregnation, as compared with the values found for the new papers *A* to *D*. The increased dielectric strength of this paper is thus perhaps accounted for by a slow loss of adsorbed ions over its long storage period.

Dielectric Loss. The dielectric loss increases 2.2 times from paper *A* to paper *D*. This is also greater than the increase in both dry paper density (1.6) and impregnated-paper density (1.38). This result is to be expected in view of the changes in conductivity discussed above. An increase in the number of ions liberated in the oil is attended by increased conductivity, increased dielectric absorption (interfacial polarization), and consequently by increased dielectric loss.

Power Factor. The power factor increases about 1.67 times over the density range *A* to *D*. This increase is less than that of the dielectric loss owing to the increase of the capacitance of the specimen with increasing paper density.

Dielectric Constant. The increase of dielectric constant over the density range *A* to *D* (see figure 2) is about 1.31 times (3.78 to 4.91). This is roughly in the same proportion as the over-all increase in the density of the impregnated paper.

Knowing the relative volumes of oil and of paper and assuming the dielectric constants to be 2.2 for the oil and 5.5 for the paper, the computed values of their combination from papers *A* to *D* are 3.08 to 3.97, if oil and paper are assumed to be in series, and 3.75 to 4.29 if oil and paper are assumed to be in parallel. The proper computed value is probably somewhere in between, giving say the average values 3.41 to 4.13 as between papers *A* and *D*. The measured values are thus substantially above the computed values.

The increase in the dielectric constant due to dielectric absorption or interfacial polarization at 60 cycles in thoroughly dried paper is only about one per cent of the geometric capacitance.[8] Data as to this increase in impregnated paper are wanting, but it is probable that the increase would be of about the same order. It appears, therefore, that in our present case the measured values of dielectric constant represent an increase over the range of density *A* to *D* which is greater than can be accounted for by geometric capacitance and dielectric absorption.

In dry paper a considerable proportion of the value of the dielectric constant is due to restricted adsorbed moisture and possibly to the motion of adsorbed ions on the surface of the paper fiber. On impregnation, these ions probably have greater freedom of motion. Some of them may be converted to conduction ions in the oil, which oscillate as space charges in the alternating field. In either case the contribution to the dielectric constant of the paper is increased, resulting in the higher measured values of the impregnated specimen as found.

Original Cause of Breakdown. As already seen initial failure begins almost invariably in the oil channels. The over-all stress at failure decreases with increasing paper density, but the stress in the oil channels at failure is approximately the same over the whole range of paper density. Increased values of stress are possible within the oil channels, due to the increased number of ions derived from the soluble and adsorbed ions in the dry paper. These ions move back and forth in clouds within the oil channels forming space charges each half cycle on opposite faces of the channel. The presence of these space charges greatly increases the local stresses at the interface between oil and paper. These stresses cause initial electric breakdown, or local thermal paths sufficient to begin the liberation of gas, and consequent spread of breakdown through the well-known processes of gaseous ionization.

Stability and Life. As stated above, initial breakdown at maximum stress is followed very promptly by complete breakdown on repeated application of voltage. Moreover these repeated values of breakdown voltage are progressively lower in value. In other words, when initial failure has once set in, the time element is practically absent in the further progress to failure.

On the other hand, the specimens frequently stand up for several hours at the maximum stress. And further, the computed values, corresponding to breakdown voltage, of oil stress in the channels, where the breakdown invariably starts, are far above the range of values at which collision, ionization, discharge, and breakdown are known to occur in oil. Both these facts strongly suggest the presence of a time element. Instability sets in at an earlier value of stress and its continued progress only results in failure at the higher value of stress.

The accelerated tests here reported, therefore, partake more of the character of dielectric-strength tests than life tests. On the other hand, it is strongly suggested that deterioration has already set in at a lower value of stress than that present at complete failure. A good test of relative stability would probably result if the increase of voltage were stopped at say 75 per cent of the maximum breakdown values as found above, and the test continued at that value.

Acknowledgments

This research, carried out in the laboratories of the school of engineering of The Johns Hopkins University is a project of the Engineering Foundation with the sponsorship of the AIEE. Grateful acknowledgment is made of the support and advice frequently furnished by both these bodies, and particularly by members of the advisory committee appointed by the AIEE to follow the course of the work.

Cordial thanks are also extended to the Union Mills Paper Company, The Sun Oil Company, the Locke Insulator Corporation, and to the Insulated Paper Cable Engineers Association for material and other forms of assistance furnished.

The burden of experimental work has fallen on Research Assistants R. B. Kaufman and C. O. Newman to whose skill and devotion much of the success of the work is due.

Summary and Conclusions

1. Accelerated life tests of a particular type as described in the paper have been carried out on samples of impregnated paper insulation. Four grades of paper were studied with a range of specific gravity 0.74 to 1.18, and all of approximately the same thickness, 0.005 inch. All specimens were impregnated with a very fluid insulating oil.

2. In accelerated life tests beginning at 400 volts per mil and with geometric increase of voltage at the rate of 3.12 per cent every four hours, the 60-cycle breakdown voltage was found to decrease with increasing density of the paper. Within the range of specific gravity mentioned, the decrease in breakdown voltage with increase of specific gravity was 30 per cent. The decrease in life was 47.5 per cent.

3. The failures almost invariably start in the oil channels between successive convolutions of the paper tape.

4. The stress in the oil channels at breakdown, as computed from the dielectric constant of the oil, and the measured dielectric constant of the impregnated-paper specimen, had approximately the same value over the range of papers studied.

5. The dielectric constant of the impregnated paper increases by 31 per cent over the range of increase of paper density, and apparently in somewhat greater proportion than as computed. The increase of the dielectric constant of the paper tapes transfers a greater proportion of the total voltage to the oil films and channels. This apparently accounts in large measure for the observed decrease in the over-all dielectric strength with increasing paper density.

6. Power factor, conductivity, dielectric constant, and dielectric loss all increase with increasing paper density. The increases are greater than can be accounted for by the increase in paper density alone. Discussion is presented suggesting that the liberation into the oil of ions adsorbed on, or contained in the fiber structure of the paper may account for increased loss and increased conductivity and may also contribute to the lowering of dielectric strength with increasing density.

Tests on Oil-Impregnated Paper—IV

Mechanism of Breakdown

HUBERT H. RACE
FELLOW AIEE

I. Introduction

IN three previous papers[1,2,3] we have presented some of the results of our studies on miniature cable specimens started in 1934. In the first two papers the relative life histories and the results of post-mortem examinations were given for (*a*) specimens saturated with gas at one atmosphere pressure, (*b*) specimens saturated with gas at 200 pounds per square inch pressure, and (*c*) specimens, gas free but under one atmosphere liquid pressure. In the third paper we presented data on fluid flow through cable paper and showed that even with high-viscosity impregnants and low-permeability papers there was sufficient flow through our specimens to prevent void formation.

It is the purpose of this paper to present observations regarding the mechanism of failure of the gas-free specimens.

II. Methods of Post-Mortem Examination

Most of the specimens were given only a visual examination after removal from their glass cells. A few selected specimens were given post-mortem examination as indicated in the first paper. However, since the first paper was written considerable improvement has been made in the microchemical technique for determining acid number and copper and lead compounds in solution, as indicated below.

A. Microchemical Determination of the Acid Content of Oil

For the determination of the acid content, approximately 0.06 gram of the oil was weighed out and dissolved in a suitable mixture of benzene and absolute ethyl alcohol, containing phenolphthalein as a titration indicator. To get rid of carbon dioxide without oxidizing the alcohol, the mixture was evaporated on the steam bath at reduced pressure to a volume near 0.5 cubic centimeter. With this small volume, the detection of the end-point was facilitated by the intensification of the color by the glass of the cell bottom. After cooling, the mixture was titrated with $N/10$ KOH (one-tenth normal solution of potassium hydroxide), with a rapid stream of dry hydrogen passing through the titration cell to avoid infiltration of CO_2, which would spoil the titration.

It was found that the acidity of these oils was extremely low, so that the actual amount of $N/10$ KOH solution per titration was around 0.0003 cubic centimeter. A microburette of 0.1 cubic centimeter capacity, graduated to 0.001 cubic centimeter and permitting the estimation of 0.0001 cubic centimeter, was employed. A precise titration technique, including optimum illumination for the determination of the titration end-point, was developed. Whenever the burette was set up for acid determinations, a blank was first run (blank = 0.0001 cubic centimeter approximately), followed by a known sample of 0.1 acid number. The titration end-point can be determined by an experienced operator to within 0.0001 cubic centimeter of $N/10$ KOH solution.

The acid content of oils is here expressed in terms of "acid number", which is the number of milligrams of KOH required for the neutralization of the acid in one gram of the oil.

The acid-number data are presented in table I, the values ranging from less than 0.01 to 0.03. Hence the acidity of all of these samples is very low. The accuracy of the acid-number determination is about ±0.005. No determinations have been made in those cases in which no values are recorded.

B. Microchemical Methods for Measuring Cu and Pb in Solution[4]

A preliminary survey of the best available microchemical methods for copper and lead determinations showed that "dithizone" (diphenyl thiocarbazone) was the most promising. Dithizone, a dyestuff, is an exceedingly sensitive reagent for several metals, and analytical methods employing it have been developed especially by Doctor H. Fischer in Germany. The smallest amounts (six gamma[*] of lead; four gamma of copper) of metals that he could determine were many times larger, however, than the amounts present in our cable oil samples. It was consequently necessary to carry through an almost complete revision of his analytical methods. We can now detect the presence of 0.1 gamma of either metal.

To achieve this sensitivity, we have made use of the General Electric recording photoelectric spectrophotometer.[5]

In the use of this instrument, the light transmission of the dithizone solution (obtained after the copper or lead treatment) is measured and recorded continuously from 400 to 700 millimicrons. The amount of copper or lead is measured by the relative displacement of the transmission curve, preferably at the most critical wave lengths, which for copper we have found to be at 508 millimicrons, and for lead at 620 millimicrons. These values are interpreted by reference to curves obtained from known amounts of copper and lead.

The following method was developed for getting the copper and lead out of the oil and into aqueous solution. An "ashless" filter paper of low and tested copper and lead content was creased and placed in a cleaned porcelain crucible. From 0.10 to 0.15 gram of the oil was applied to the top of the innermost creases of the filter and weighed. In this manner, the loss of oil by creeping on the sides of the crucible was prevented. The oil and paper were ashed by careful heating on a covered hot plate, the temperature being gradually increased and gentle suction applied to withdraw the oil vapors. The ash was finally treated with a small amount of perchloric acid and made up to the proper concentration in distilled water.

1. *The Copper Determination.* When an acidified aqueous solution of copper salts is shaken with a solution of dithizone, the copper combines with the dithizone, changing the green dithizone into the pink copper compound. We have found it convenient to determine the amount of this pink copper compound without removing the excess of green

The vertical line in test number 1 indicates the number of layers showing numerous punctures resulting from general ionization in oil between layers. Where no vertical line is shown there was no evidence of this general ionization.
In tests numbers 2, 3, and 7, portion 4 is from the oil in the cell surrounding the specimen.

* Layer full of carbonized spots.

dithizone. The colors of these CCl_4 layers varied from green (little or no copper) to pink (3.5 gamma of copper; little or no dithizone). The actual extraction of the copper was carried out in volumes near one cubic centimeter; the CCl_4 layer thus obtained was then diluted to 27 cubic centimeters and the transmission measured by the spectrophotometer. The strength of the dithizone reagent was always adjusted so that its CCl_4 solution transmitted approximately 70 per cent of the incident light at a wave length of 508 millimicrons. Corrections for the copper in the paper and reagents are applied in the final calculation. The determination is accurate to approximately one gamma of copper.

2. *The Lead Determination.* In the copper determination the lead present does not combine with the dithizone, but remains in the aqueous layer. The latter is transferred to a flask (made of nonlead glass) and made alkaline with ammonia, then shaken with the dithizone solution. The lead unites with the dithizone to produce a pink CCl_4 solution. Further shakings with potassium cyanide assure the elimination of any other metals and the removal of the excess dithizone.

The sensitivity of the determination is considerably improved by converting the pink to green by a final acidification. Hence the light transmission of this green solution is measured in the spectrophotometer and the lead concentration calculated. Corrections are applied for the lead in the paper and in the reagents. The determination is accurate to approximately one gamma of lead.

3. *The Determination of Copper and Lead in Paper Samples.* In the cases of nine of the samples, portions of the cable

test papers, after centrifuging, were tested for copper and lead in the same manner as were the oils. A strip of paper approximately 0.25 inch wide and one inch long (weighing about 0.03 gram) was cut out laterally in each case, weighed, ashed, and treated with dithizone.

The brownish-black striations observable on the number 1 papers (copper end) persisted as black striations in the ash.

III. Post-Mortem Chemical and Electrical Data on Ten Specimens

Table I gives the results of very careful microexamination of selected specimens having a range of life from 0 to 781 days at 30 kv. All measurements were made as soon as possible after opening the cell. The electrical measurements were made in the manner previously described.[1] In test number 1 electrical measurements were made of a one-inch strip of oil-soaked paper cut from the test section as far as possible from the puncture, extending from layer *A* next to the inner copper electrode to layer *J* next to the outer lead electrode.

The vertical line indicates the number of layers showing numerous punctures resulting from general ionization in the oil between layers. In general, layers showing visual effects of ionization also showed high power factor even though the portion tested contained no carbonized spots. (See discussion of figure 3 and figures 7, 8, and 9.)

Test number 2 shows electrical measurements made on portions of oil centrifuged from (1) the inner two layers next to the copper, (2) the center layers, and (3) the outer two layers next to the lead.

The technique previously used for the acid-number measurements (test number 3) has been considerably refined as already indicated. Tests numbers 4, 5, and 6 used in the 1935 studies[1] were not used because the previous results were of so little value. The new colorimetric microchemical methods described earlier in this paper for quantitative determination of Cu and Pb in test number 7 are about 100 times as sensitive as the spectroscopic methods previously described.[1] Also in addition to determining the metals in solution in the centrifuged portions of oil, test number 8 has been added in which the metal content has been determined for portions of paper from (1) the inner layers next to the copper, (2) the middle layer, and (3) the outer layer next to the lead.

A study of table I leads to the following conclusions concerning chemical changes during life.

1. Acid number of all specimens examined was extremely low, even including specimen number 225 containing used oil. Therefore, either no acids are formed in the absence of oxygen during these extreme life conditions or, if formed, they react with the metals as rapidly as they are produced.

2. Portions of centrifuged oil contain only very low concentrations of either Cu or Pb and in a given specimen the concentration of metal soaps dissolved in the oil is fairly uniform. This may indicate saturation conditions for metal soaps dissolved in each specimen.

3. The paper, on the other hand, contained large amounts of both metals particularly in the inner and outer layers. The presence of copper on the paper in contact with the Cu electrode and the presence of Pb on paper in contact with the electrode might be explained by the adhesion of free metal particles. However, this assumption will not explain the finding of large amounts of copper in the layer next to the lead electrode and of lead in the layer next to the copper electrode in all of the long-life specimens examined, nor will it explain the presence of lower concentrations of both metals in the intermediate layer. New samples of papers *D* and *M* were checked for metal content and no detectable amounts of either were found ($<1\times10^{-6}$ gram per gram paper).

4. The last two observations lead to the

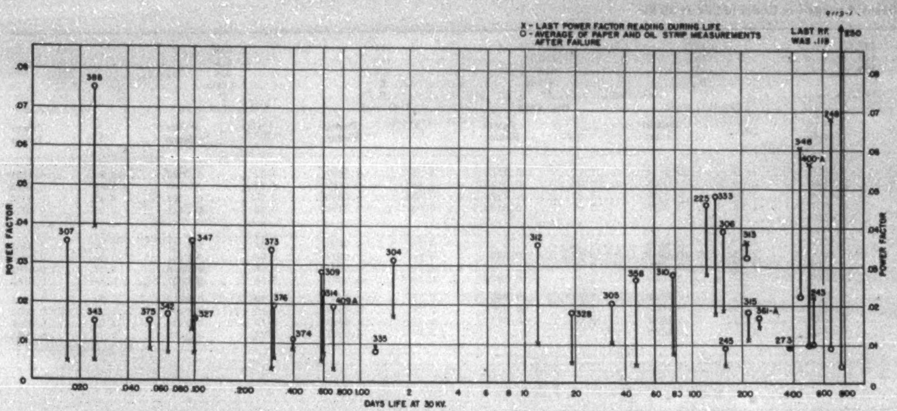

Figure 1. Study of life versus dielectric loss before and after failure

conclusion that although the concentration of metal soaps in oil is normally low, these compounds diffuse through the specimen because of temperature cycles and the electric field and are deposited in the layers of paper next to the electrodes.

In a further attempt to determine whether increasing dielectric losses during life result from deterioration of paper or chemical changes in the oil, strips of oil-soaked paper from several specimens were benzene extracted after the usual post-mortem electrical measurements. These were measured dry and then three of the strips were reimpregnated with new oil *A* and measured again. The results are shown in table II. Too few data have been obtained to warrant definite conclusions. However, the materials responsible for high losses and partly removed by benzene extraction probably resulted from chemical changes in the oil rather than the paper. On the other hand, the power factor of the layers of paper next to the metals remained higher than for new paper both after extraction and after reimpregnation. Thus high-loss materials which are insoluble in benzene must have been formed or electrolytically deposited in these layers of paper.

IV. Post-Mortem Electrical Data on 30 Specimens

In addition to the specimens shown in table I in which separate studies were made of the inner, middle, and outer layers, electrical measurements were made on bulk oil and on oil-soaked paper strips from 20 additional specimens. Figure 1 has been plotted from these electrical data to study any possible correlation between power factor and life. All specimens on which post-mortem electrical measurements were made that had a life at 30 kv greater than 0.01 day have been plotted. To show gradual changes of power factor with time, the life histories of the six longest-life specimens have been plotted in figure 2. A study of these data leads to the following conclusions.

1. There is no correlation between power factor before failure and life.

2. In all but the specimens having longest life (313, 273, 348, 400*A*, 243, 248, and 250) the post-mortem power factor was considerably higher than the last life measurement, indicating that the deterioration leading to failure occurred during a relatively short time.

3. In specimens 313, 348, 400*A*, 243, 248, and 250, which had very long life, the post-mortem strip measurement was lower than the last life measurement. All of them showed very gradually increasing power factor during life. None of the longest-life specimens showed general ionization. Also, the strip for post-mortem examination was always taken as far as possible from the puncture. Therefore it is evident that *in these six specimens the cause of failure was gradual local chemical deterioration in the region which eventually failed but not materially affecting the portion later used for the strip measurements.*

V. Visual Examination of 30 Specimens

The most striking result of visual examination is the evidence of what we shall call "general ionization" occurring in the oil spaces between layers of paper and starting at the inner electrode. Typical examples are shown by the photographs reproduced in figures 7, 8, and 9 of specimens 305, 343, 374, and 421, whose make-up and life are given in table III.

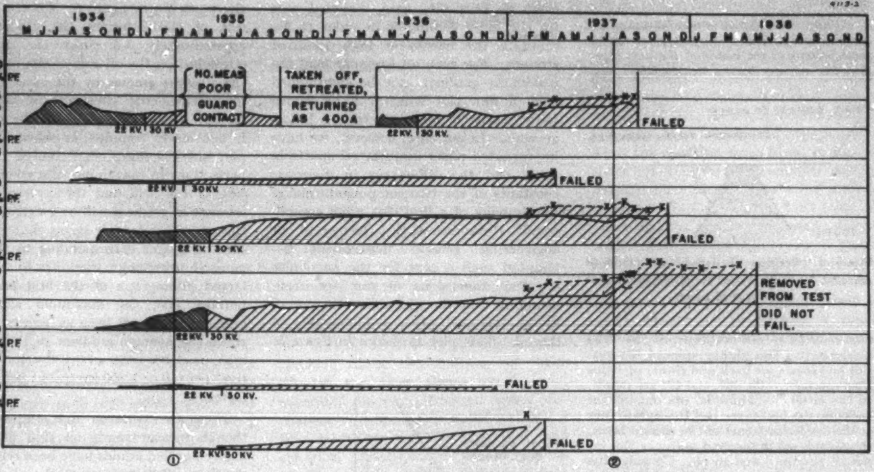

Figure 2. Power-factor life histories of six longest-life specimens

Solid curve—Power factor measured at 6 kv at maximum oven temperature

Crosses—Power factor measured at 30 kv at maximum oven temperature

①—Started daily heating cycles, room temperature to 60 degrees centigrade

②—Raised maximum oven temperature to 100 degrees centigrade

For comparison, the photograph of specimen number 212, which was removed for examination after 146 days at 30 kv, shows no evidence of such ionization. This is also true of 12 out of the 15 specimens having lives over 40 days, as is shown by figure 3, in which are plotted the number of layers, starting from the inner electrode, through which such multiple punctures had occurred.

A careful scrutiny of all specimens leads to the following definite observations:

1. *For every puncture visible in any layer of paper there is a corresponding hole or conducting spot through every intervening layer to the inner electrode*, that is, in no specimen did we find a single carbonized spot which had no conducting path to the inner electrode. It is true that branching paths were numerous, as shown by number 327 and the enlarged photograph of number 374, but these could all be traced back to the inner electrode.

2. *The inside of the first layer, that is, the surface that had been in contact with the inner electrode always shows dark markings corresponding to the lines of contact of the paper and the threads on the inner conductor.* The enlarged photograph of the portion within the circle of number 305 is typical and shows that when the paper was in close contact with the edge of the tooth, the marking occurred as a double line just away from

Table III. Data for Specimens Shown in Figures 7, 8, and 9

Specimen Number	Days Life 22 Kv	Days Life 30 Kv	Impregnant	Paper	Thickness (Inch)	Layers	Density	Gurley Air Flow

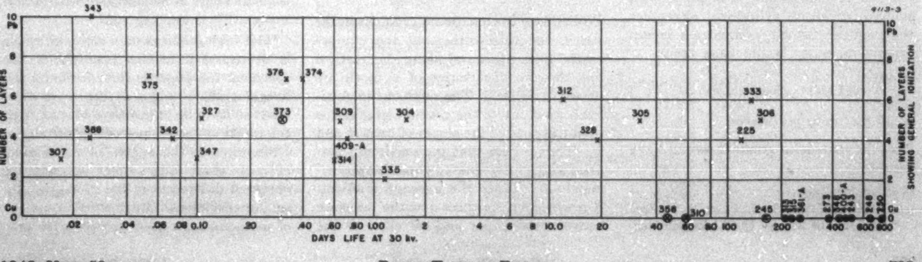

Figure 3. Number of layers through which numerous punctures had been caused by general ionization

each side of the area of contact, as sketched in figure 4.

3. *Where carbonization or wax formation had occurred, the outside of any layer shows the same pattern as the inside of the next layer, these two surfaces having been together, separated only by a hin but finite oil film.* To illustrate this fact photographs of the outside and inside (or back and front) of strips from specimens 305, 327, and 421 are shown. In the latter, for example, the outside (or back) of the first layer has the appearance of the inside (or front) of the second layer, the outside of the second matches the inside of the third and so on. Consider the spot marked (1) on the inside of the third layer. The corresponding spot on the outside of this same layer is marked (3) but corresponds in appearance to the spot marked (2) on the inside of the fourth layer. The corresponding spot on the outside of this layer is marked (4) and corresponds in appearance to the spot on the inside of the fifth layer, marked (5). Here the pattern stops since this particular incipient failure did not get through the fifth layer of paper before the specimen finally punctured in an entirely different spot. The enlarged photographs of the inside and outside surfaces of the area shown in the circle on specimen number 343 illustrate this same observation.

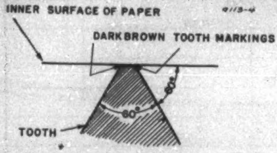

Figure 4. Position of dark-brown markings adjacent to tooth edge on inner surface of first layer of paper

4. *In many specimens carbonization appeared to have occurred over considerably larger areas in layers away from the electrodes than in layers adjacent to the electrodes.* This is illustrated to some extent by all the specimens shown.

5. *The outer five or six layers were usually punctured by but a single hole with little evidence of progressive carbonization.* This also is illustrated by all the specimens shown.

VI. Maximum Electrical Gradient

If our specimens had been made with smooth concentric cylindrical electrodes the average gradient, assuming a homogeneous dielectric, would have been

$$\frac{30{,}000}{65}=461 \text{ volts (effective)/mil}$$

or 257 kv (peak)/centimeter.

Also, the maximum gradient would have been

$$G_1=E/r_1 \log_e (r_2/r_1)$$
$$=30{,}000/187.5\times 0.3=533 \text{ volts (effective)/mil or 297 kv (peak)/centimeter.}$$

In designing the test specimen, however, we purposely used threaded rods for the inner conductor in order to accentuate the effects of high localized stresses. For such an irregular field the maximum gradient can be determined from a flux plot which can be drawn fairly easily if the dielectric is homogeneous. In our case, however, we have impregnated paper and free oil spaces in series and the differences in dielectric constants of the two components makes the drawing of a flux plot more complicated. Nevertheless, S. I. Pierson of our engineering general department attempted such a plot for the particular physical dimensions of our specimen, assuming that the dielectric constant of the impregnated paper is double that of the oil. This plot is shown in figure 5.

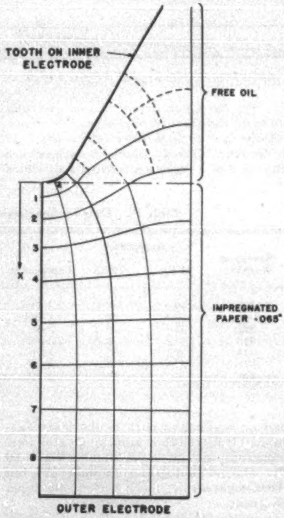

Figure 5. Flux plot for determining gradient

To estimate the maximum gradient in the paper, the intersections of the equipotential lines measured along the vertical line through the center of a tooth are drawn in figure 6. The ratio of the maximum gradient to the average gradient is then the ratio of the slopes of lines *A* and *B*. Thus we see that the maximum gradient in the impregnated paper is approximately 3.5 times the average gradient. Now consider the point *a* at the interface between the paper and oil close to the point of contact between the paper and the tooth tip in figure 5. On the paper side of this interface the gradient is approximately 3.5 times the average stress but on the oil side of the interface the stress is greater by the inverse ratio of the dielectric constants of the two media. Again if the edge of the thread is not nicely rounded as shown in the plot but has sharp edges caused by imperfections in machining, the concentration of the field and the corresponding increase in gradient will be greatly accentuated. Therefore, it seems that for the thin oil spaces corresponding to the regions showing color markings in the enlarged photograph of the first layer in number 305, the maximum electrical gradient may have been as high as seven times the average gradient in the specimen, or of the order of 3,200 volts (effective) per mil or 1,800 kv (peak) per centimeter.

These are extremely high gradients although measurements on thin films of highly purified liquids have been reported showing dielectric strengths between 1,400 and 1,800 kv (peak) per centimeter.[7,8] Also, in some unpublished experiments we have obtained dielectric strengths of the order of 1,200 kv (peak) per centimeter in 0.025-inch gaps.

At some fairly definite high gradients it is evident that even gas-free liquids break down by ionization (so-called), but little is known about the actual mechanism and the controlling factors. From work on crystals, Von Hippel[9] states that "Our picture of the breakdown mechanism is developed for the condensed phases in general. It covers, therefore, the liquid insulators too, but the high mobility of the particles will certainly bring some new features in the situation. If suddenly space charges form by electron emission or impact ionization in the neighborhood of the electrodes, the electrostatic repulsion may overcome the surface tension and bubbles may form in this manner without the presence of occluded gases." If this hypothesis is correct there is little argument about subsequent steps in the breakdown mechanism.

This high gradient on a series oil space is decreased if in the assembly of the specimen the paper is forced around the irregular sharp edges of the inner electrode so as to be in intimate contact with the metal at the regions of highest stress. Differences in the degree of enveloping of such sharp edges may account for observed differences in life of supposedly similar specimens. In practice a number of methods have been proposed for pro-

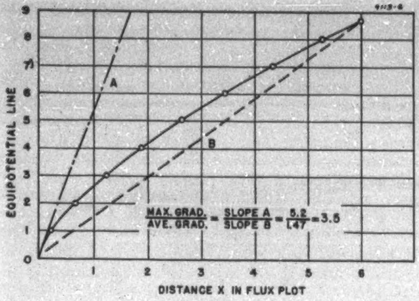

Figure 6. Curves of calculation of maximum gradient from flux plot

viding a smooth cylindrical equipotential surface at the inner conductor, for example, lead sheathing, or covering with copper tape or metalized paper[10] in order to eliminate such high-stress regions and raise the corona starting voltage for a given total thickness of insulation.

VII. Apparent Mechanism of Failure

A number of writers have discussed the mechanism of failure of impregnated paper cables. We shall not attempt a summary of their statements although a few recent references are given.[10–14] Also, an excellent summary of new developments and improvements in high-voltage cables is given in a series of articles in *The Engineer* starting with the August 6, 1937, issue.

From the evidence presented above we believe that the failures of our gas-free oil-filled specimens can be attributed to two distinct and independent causes, the sequence of events being somewhat as follows:

A. Ionization

If the physical conditions are such that the electrical gradient at the surface of the inner electrode is greater than the dielectric strength of the liquid, ionization in the form of localized sparking causes puncture of the first layer of paper at local hot spots. Also, the action of the corona gradually decomposes the impregnating oil, liberating gas and causing condensation to form wax. The effects of electrical bombardment of organic liquids has been given considerable study[15–18] and need not be discussed here. The generation of gas may or may not accelerate the breakdown, depending upon factors such as the rates of evolution and absorption, pressure developed, migration of liquid during heating and cooling cycles, and the like. In any case, progress of the incipient failures in our specimens is dependent upon the burning of holes through the paper sheets by the heat generated in such localized spark discharges. If the paper could withstand the discharges without chemical and electrical deterioration the specimens would not fail. Now a carbonized hole through the first layer of paper constitutes a sharp-pointed extension of the inner electrode and the resulting high electric gradient causes the spark discharges at its terminus to bore progressively through the layers of paper toward the other electrode (electron drilling, as it were). The speed with which this progresses depends upon a number of counterbalancing factors such as the intensity of the discharge, the density of the paper, the quenching action of the impregnant, and the like. The appearance of many of the specimens (see photograph of number 374) indicates that after the spark discharges have punctured several layers of paper the electric field distribution about such a carbonized path is no longer purely radial but has large tangential components. Thus the sparking spreads out in the oil space between two layers of paper causing damage over much wider areas until a weak spot is found in the next layer of paper and the process is repeated. Eventually, however, enough layers of paper will have been broken down to raise the potential gradient across the remaining good layers to the point where a quick failure occurs forming a single small radial puncture through the remaining layers, as shown in the photographs. The mechanism of this final failure is probably thermal since the average gradient is only of the order of 1,000 volts (effective) per mil, which is well below usual values for impulse or disruptive breakdown for oil-impregnated paper.

This entire picture agrees with the conclusions of Doctor Robinson's[10] work as to the mechanism of failure in solid-type cables. However, there are two major differences in conditions. First, we do not assume that ionization started in voids or gas pockets since our specimens were very thoroughly dried and impregnated, being degassed in the process to about one micron pressure. Further-

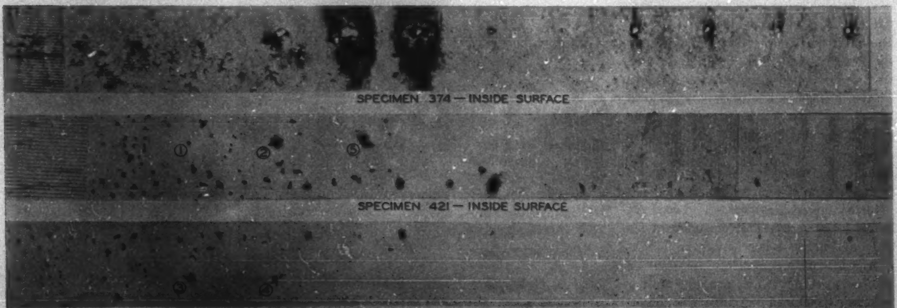
Figure 9

more, they were kept in sealed glass cells during their entire life so that there was no chance for leakage of gas from the outside. Thus, if gaseous ionization occurred, the gas must have been generated within the cell. Second, we used a continuous sheet of paper wrapped around the inner electrode to give the desired total insulation thickness so that there was no chance for creepage around tapes as is commonly found in commercial cable and each layer of paper had to be punctured before the next layer could be attacked by a spark discharge starting at the inner electrode.

With these modifications, the evidence indicates that the great majority of our specimens failed by ionization resulting in spark discharges beginning at the inner electrode and progressively burning through successive layers of paper.

B. Chemical Deterioration

The mechanism just described accounts for the failure of all the specimens reported in this paper except a few of the longest-life specimens (see figure 3). These latter specimens were prepared by special methods so that the inner layers of paper were formed around the sharp edges of the threaded inner electrode, thus putting solid dielectric instead of oil in the regions of highest stress. This difference apparently prevented ionization at the surface of the inner electrode at the operating voltage and al-



SPECIMEN 374—INSIDE SURFACE
①
②
③

SPECIMEN 421—OUTSIDE SURFACE

lowed chemical deterioration to be the ultimate cause of failure. Our picture of this process is as follows:

From part IV, including tables I and II, it is evident that even in the absence of ionization and free oxygen, very slow chemical deterioration occurs under the extreme conditions of temperature and electrical gradient used. This slow deterioration results in gradually increasing dielectric loss in localized regions until such regions become thermally unstable and a typical thermal failure results. That these effects are localized is shown by the fact that the post-mortem strip measurements on specimens 348, 400*A*, 243, 248, and 250 gave lower dielectric loss than that shown by the whole sample before failure (see figure 1). That this chemical deterioration involved metal compounds which migrated through the paper was shown by the copper and lead determinations (see tables I and II).

However, in the absence of ionization and in the absence of free oxygen the rate of chemical deterioration was so slow that the longest-life specimen was subjected to a maximum gradient of at least 1,800 volts (effective) per mil or 1,000 kv (peak) per centimeter for about two years before failure. This is so far above commercial operating conditions that we believe that *in practical service chemical deterioration can only become a contributing factor to failure after extremely long life or when oxygen or oxidized oil is accidentally admitted to the cable.*

VIII. Conclusions

1. Our gas-free oil-impregnated miniature cable specimens were subjected to extremely high electrical gradients. Calculations indicated gradients in the oil at the interfaces between the inner electrode and the paper as high as 3,200 volts (effective) per mil or 1,800 kv (peak) per centimeter.

2. Under these conditions the most important cause of failure was ionization in the oil leading to spark discharges and carbonization of the paper, beginning at the inner electrode.

3. Where special construction was used so as to minimize the maximum gradient in the oil and thus prevent ionization, chemical deterioration gradually caused failure by thermal instability after extremely long life.

4. The fact that carbonized areas were not found which had no direct connection by a conducting path to one of the electrodes indicates either that under the conditions of our tests local ionization does not start within the body of the impregnated paper or that even if it did occur the amount of energy which can be fed to such a spot through the intervening good dielectric is insufficient to cause carbonization. In solid-type cables ionization within the body of the impregnated paper is known to exist because of observed wax formation but under normal voltage such ionization does not lead to failure except as spark discharges start from the electrodes causing progressive carbonization of the paper layers.

This is in agreement with statements made by other students of mechanisms of cable failure (see, for example, pages 26 and 101 of reference 10).

5. These experiments indicate that in commercial gas-free oil-filled cable the usual operating potentials are well below ionization gradients so that ionization failure can only occur if the cable is incompletely degasified when installed or gas is accidentally admitted. Also, chemical deterioration can only become a contributing factor to failure after extremely long life or when oxygen or oxidized oil is accidentally admitted.

Dielectric Strength of Insulating Liquids in a Continuously Circulating System

HUBERT H. RACE
FELLOW AIEE

THE electrical properties of liquid dielectrics have been studied by theoretical and experimental physicists for a long time. Of the various properties one of the most important, and probably the least understood, is the mechanism of electrical breakdown. To become acquainted with the voluminous literature in this field one must read not only monographs[1-4] but also more recent important summaries and experimental contributions.[5-11] One of the important concepts in the past has been that breakdown is initiated by ionization in gas bubbles thrown out of solution or suspension in the liquid. As a new experimental approach to this problem we set up a closed system in which the liquid could be continuously circulated through the dielectric strength cell with filters, dryers, and a degasifier in series in the system so that solid particles, moisture, and dissolved gas could be removed. Arrangements were made so that the partial pressure of gas in solution could be varied from <0.01 micron to one-atmosphere pressure. Another object of setting up a continuously circulating system was to determine whether progressive removal of residual gas, moisture, and floating particles would decrease the mean deviations of successive breakdown measurements. Further, because of the usual large spread in dielectric strength measurements on liquids it was deemed important to obtain a large number of shots so that statistical methods of analysis could be applied to the results. The system was provided with automatic controls, time-delay relays, and a voltage recorder so that periodic breakdown measurements could be made and recorded at predetermined intervals without the tedium of continuous attendance by the operator.

Apparatus and Experimental Procedure

Circulating System

The system devised to continuously circulate, filter, and degasify the liquid to be tested is shown schematically in figure 1. The pump and speed control reservoir are connected to the glass system by Fernico-glass seals. The vacuum-tight liquid pump was developed by F. S. Cooper of our laboratory and is shown in detail in figure 2. The top and bottom plates are rigidly mounted, while the center oscillates vertically. The valves are made of aluminum and are light enough so that a few centimeters head of oil is sufficient to lift them. With a vertical motion of one centimeter or less the Sylphons should operate indefinitely without mechanical trouble. In order to use a reciprocating pump to give continuous flow in a closed hydraulic system a flexible storage reservoir was provided to maintain a constant pressure on the

liquid. The details of this reservoir are shown in figure 3. The vertical rod mounted on the lower end of the Sylphon has collars (*a*) and (*b*) which limit its motion in the fixed guide (*c*). Normally, however, the travel is held within narrow limits by automatically controlling the speed of the pump motor through the contacts (*d*). When the upper contact is made the motor speed is increased. When the lower contact is made the motor speed is decreased again. The wiring diagram of the speed control circuit is shown in figure 4.

Referring to figure 1, the jet into the degasification chamber was designed so that there will be one-atmosphere pressure drop at normal pumping speed. Thus the pump maintains one-atmosphere hydraulic pressure on the liquid passing through the test cell even though a good vacuum is being maintained in the degasification chamber.

For some of the experiments the back pressure of gas in this chamber was increased as high as one atmosphere. To maintain the same rate of flow the hydraulic pressure had to be increased accordingly. This was accomplished by adding lead weights (*e*) on the pan in figure 3, thus adding to the force on the pressure-control reservoir. For back pressures of gas between zero and one atmosphere the weights were adjusted to give approximately the same rate of liquid flow so the hydraulic pressure in the test cell in each case was roughly equal to one atmosphere plus the partial pressure of gas.

ELECTRICAL CIRCUITS

The wiring diagram for the 60-cycle power circuit is shown in figure 5 with the necessary push-button stations and relays for manually or automatically raising and lowering the voltage by means of a motor-driven regulator.

To remove the voltage as quickly as possible after a breakdown occurs, the thyratron trip circuit shown in figure 6 was used.

For d-c measurements a 60-kv kenotron was used with a smoothing capacitor consisting of five 0.25-microfarad capacitors in series. A 260-megohm resistor was used to grade the potential along the capacitors to ground and to provide a definite load on the kenotron.

Several items of auxiliary equipment were assembled for use with this set which deserve recording.

Because of the poor regulation of the X-ray transformer used as a power source it seemed imperative to measure the potential applied to the testing cell directly on the high side of the transformer. A capacitance divider was built as shown in figure 7. The spheres are spaced far enough apart so that they will not arc over at the upper limit of voltage E_1 of the set. They are rigidly mounted so that the capacitance to the measuring section is constant. This fixed measuring capacitance C_1 is connected in series with a low-loss capacitor C_2 of such a value that the maximum voltage E_2 across C_2 will be 150 volts by the relation $(E_2/E_1) = (C_1/C_2)$. The voltage E_2 is then measured by a vacuum-tube voltmeter. This scheme is possible because the vacuum-tube voltmeter is essentially an infinite impedance device and can measure E_2 even though the capacitance-charging current is very small. Also the vacuum-tube voltmeter measures peak voltages independent of wave shape or frequency. Calibration curves for the capacitance divider with vacuum-tube voltmeter and the primary voltage recorder are shown in figure 8. This calibration does not apply to data taken previous to October 17, 1937.

When making repeated d-c breakdown measurements the total energy stored in the smoothing capacitors was discharged through the testing cell at each shot. This caused much more gas evolution and carbon formation on direct current than on alternating current and caused successive shots to be increasingly lower unless very long circulating times were allowed between shots. Therefore, the

Figure 8. Calibration curves (using 12.5-centimeter spheres) for capacitance divider with vacuum-tube voltmeter (circles) and primary voltage recorder (crosses)

For some of the d-c tests we measured current in the test cell with a sensitive microammeter. Two methods were tried for protecting the instrument if a breakdown occurred while the instrument was connected to the ground side of the test cell. The simplest scheme was to connect a small Thyrite protective gap across the instrument. Another scheme is shown in figure 10. The instrument is protected from steep transients by a filter circuit until the *FG*-17 tube can cause the short-circuiting relay to close, thus shunting the impulse current to ground.

Testing Cells

A typical cell using hemispherical molybdenum electrodes is shown in figure 11. The incoming liquid is directed through the gap. The outlet is placed at the top so that gas formed during a discharge will be carried out to the degasification chamber. The glass cell wall is broken below the lower electrode by a fused-in Fernico ring, so as to eliminate surface leakage when measuring current.

Experimental Results

Improvement in Transformer Oil Caused by Heating

Figure 12 shows the last third of the breakdown measurements made on a three-liter sample of transformer oil drawn from commercial storage and put into the circulating system without any purification other than degasification. In about a week of continuous circulation, 1,380 dielectric strength measurements were made on this sample. One significant observation is that the continuous removal of the products of decomposition by evacuation and filtration leaves the remainder of the liquid as good as ever so that the final measurements were as high as any. My interpretation of the gradual improvement obtained during the first 260 measurements shown in figure 13 is that continued heating gradually removed moisture. This is confirmed by the fact that when the temperature was lowered to 30 degrees centigrade at the end of the run the improvement was retained. A probability plot

of the last 99 measurements is shown in figure 13.

Decomposition products resulting from one arc have a marked effect on the next breakdown measurement unless sufficient circulation time is allowed between measurements for the washing of such products out of the test cell.

To limit the amount of energy dissipated in the cell for each shot a 10^7-ohm resistor was connected in series with the high-voltage lead to the cell at shot 950. Shots 1020–1030, 1140–1160, and 1200–1220 show conclusively the deleterious effects of such products when the circulating time between shots is short. Therefore the current-limiting resistor was used for subsequent measurements.

Effects of Varying the Partial Pressure of Air in Solution From < 0.01 Micron to One Atmosphere

Figure 14 shows a series of measurements on a synthetic high-boiling liquid composed of 73.5 per cent diphenyl oxide and 26.5 per cent diphenyl manufactured by the Dow Chemical Company, and given the trade name Dowtherm. The liquid, as received, contained an undesired amount of conducting contaminants so that it was necessary to purify the sample by fractional distillation in a five-foot packed column at 20 millimeters nitrogen pressure, the fraction saved having a boiling range from 133 to 134 degrees centigrade at this pressure. The important and entirely unexpected result of this series of measurements is that *changing the partial pressure of air in solution from < 0.01 micron to one atmosphere had no effect on the dielectric strength.* This is contrary to the results of many previous investigators so that it is important to point out several major differences between these and previous experiments.

(*a*). Routine dielectric strength tests made in this country are usually taken in an open cell with sharp-edged one-inch electrodes spaced 0.1 inch apart. Thus the maximum gradient at the edges of the electrodes is unknown. Also, the average of several shots is taken without removing the products of decomposition, and further, the tests are made in open cells with little provision for eliminating moisture or floating contaminants. While such measurements may serve a useful purpose in detecting the presence of gross contamination, they cannot characterize the ultimate dielectric strength of a particular insulating liquid.[16] For example, Clark[8] in his figure 8 reports a dielectric strength for transformer oil at one

Figure 14. Effects of varying the partial pressure of air in solution in Dowtherm from <0.01 micro to one atmosphere

Most probable—835
Standard deviation—14.4 per cent

atmosphere pressure of about 220 kv peak per centimeter, which is very much lower than the most probable value shown in figure 18 of this paper for similar oil.

(*b*). For the experiments reported in this paper the liquid in the test cell was maintained during continuous circulation at a hydraulic pressure of one atmosphere plus the partial pressure of gas in solution. Thus the hydraulic pressure was varied from one to two atmospheres while the partial gas pressure was varied from <0.01 micron to one atmosphere. The inhibition of free gas-bubble formation by the superimposed hydraulic pressure probably accounts for the fact that we found no dependence between dielectric strength and partial gas pressure. This is in agreement with experiments[6,9] showing that gas in solution has no effect on breakdown but contrary to much of the data reported in the literature.[5,8,13] Figure 15 shows a probability plot of the last 99 shots from figure 14. While the order of magnitude of dielectric strength is high we have not yet eliminated one or more uncontrolled factors resulting in an average deviation of 14 per cent. Figure 16 shows another set of measurements which indicate that in our system varying the partial gas pressure has no effect on the dielectric strength of either a low viscosity cable oil alone or mixed with ten per cent of Dowtherm. Figures 17 and 18 show probability plots indicating no appreciable difference between the oil alone and with ten per cent Dowtherm.

(*c*). Another major difference between this and previous work is that for most of our measurements the liquid was being forced through the test gap while voltage was being applied. Figures 19 and 20 show that when circulation was continued while voltage was being applied the breakdown strength was 35 per cent greater than when the circulation was stopped during the measurement even though in both cases 36 minutes continuous circulation was allowed between successive shots to clean out decomposition products. Two possible explanations suggest themselves: Perhaps forcing the liquid through the gap may have had a beneficial effect in sweeping away minute solid suspended particles which were too small to be removed by the filter. If such particles having dielectric constants higher than oil remain in the field they would distort the field and be attracted to the electrode surface, and thus increase the maximum electrical gradient in the liquid. Another possibility is that hydraulic pressure has some effect since with circulation the pressure was greater than 76 centimeters but without circulation the oil head gives a pressure of the order of 15 centimeters. As yet we have insufficient data to determine whether either of the above suggestions is the real cause of the observed difference in breakdown strength with and without circulation.

Effects of Conditioning at a Fixed Voltage for a Predetermined Time Before Increasing Voltage to Breakdown

All of the breakdown measurements reported so far have been made by applying a voltage which is increasing continuously at the rate of approximately 2 kv

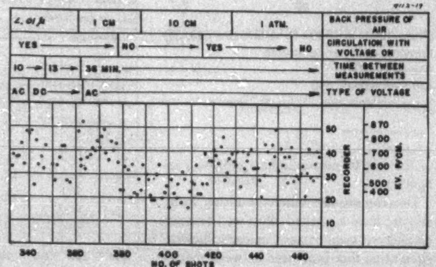

Figure 19. Dielectric strength of Dowtherm with and without circulation while applying voltage

Cell number 1, one-inch molybdenum electrodes, 0.028-inch (0.071 centimeter) spacing; data 4/21/38 to 4/24/38 peak per second. The question arose as to the conditioning effect of holding the voltage at a predetermined value below the expected breakdown point for a predetermined time, after which the voltage would again be increased at the usual rate to breakdown. To accomplish this a time-delay relay was inserted in the regulator motor circuit actuated by a voltmeter contact on the photoelectric recorder[15] which could be set at any predetermined primary voltage. Figure 21 shows data taken with and without such a conditioning period. Cells with different spacing between electrodes were connected in series in the system with results as shown. Shots 38–90 show again the previously noted decrease in breakdown strength when the liquid was not being circulated while voltage was applied. Between shots 90 and 108 the voltage was allowed to rise to 523 kv peak per centimeter and then was held at this value. For all but the 98th shot breakdown occurred within nine minutes. The conditioning voltage was lowered to 476 kv peak per centimeter and breakdown did not occur within nine minutes for about half the shots. The time intervals for both clean-up circulation and partial voltage conditioning for two groups of shots are shown in figure 22. Apparently under the conditions of our tests, breakdown is a probability function of time of voltage application as well as the magnitude of the gradient. From the very limited data available we found that with five-minute circulation clean-up intervals and when conditioning at a gradient approximately 50 per cent of the maximum value obtained on a short-time test, there was a 50 per cent probability that failure would occur within nine minutes. (Shots 109–131.) Later with circulation clean up intervals of about 14 minutes and with a conditioning gradient of approximately 65 per cent of the maximum value obtained on a short-time test, there was a 50 per cent probability that failure would occur within 33 minutes. (Shots 155–173.) It should be very interesting to study these time-gradient relations with different types and conditions of electrodes and with variations in the physical and chemical purity of the insulating liquid.

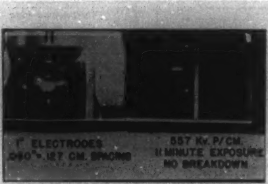

Figure 24. Photographs of electroluminescence

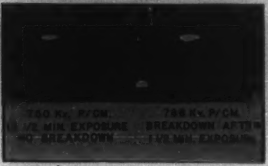

Figure 25. Photographs of electroluminescence

"Electroluminescence" in Dowtherm Preceding Breakdown

One evening we noticed that a *diffuse blue glow* appeared between the electrodes at roughly one-fourth of the breakdown voltage and continued with increasing brilliance up to breakdown. No attempt was made to obtain the spectral distribution of the light emitted. At first we called it fluorescence since to the eye the color was the same as that observed in the same liquid under X-ray or high-pressure mercury-arc excitation. However, since the glow has an electrical origin the name "electroluminescence" is suggested.

This phenomenon appeared to be entirely different from spark discharges occurring in cells containing solid dielectrics in series with the liquid, although the lowest threshold gradient was about 160 kv peak per centimeter (see figure 23), which is only slightly lower than the value of 200 to 250 kv peak per centimeter given by Conradi.[16] Under conditions where electroluminescence did not occur we occasionally observed incipient spark discharges or *vorentladungen*[14] immediately preceding breakdown. Here again the appearance and, I believe, the causes of the two effects are entirely different. Several attempts were made to obtain electroluminescence in mineral oils with no success. Also a number of runs were made in an attempt to determine the critical conditions necessary to produce it in Dowtherm. The most important observation was that a few centimeters partial gas pressure of either air or CCl_2F_2 would completely quench the glow. This is illustrated by visual observations of luminescence starting points recorded in figure 23 for shots 120–144. For these observations black cloth was wrapped around the cell and a Herkolite tube was extended from the cell to a hole in the high-voltage cage so that an observer could look at the cell with a minimum of stray light. The crosses indicate the recorder voltage at which the observer could first see a glow in an otherwise black field. This threshold increased as gas was admitted until at ten-centimeter partial pressure no glow was discernible before breakdown. However, the glow reappeared as soon as evacuation was started again and the threshold decreased as the partial pressure of gas remaining in solution was decreased.

Another interesting observation was that as gas was admitted the glow not only decreased in intensity but also appeared to be concentrated adjacent to both electrode surfaces, leaving a dark space between them. Unfortunately the breakdown voltages were low for this set of observations, resulting, I believe, from short clean-up intervals between shots and large amounts of energy dissipated in the cell per shot since the d-c smoothing capacitors discharged through the cell. A few subsequent breakdown measurements, taken with a high-voltage thyratron to short-circuit these capacitors to ground (see figure 9) as soon as possible after breakdown, indicated no significant difference between 60-cycle peak and d-c breakdown voltages.

Since, as far as we knew, such a glow in an insulating liquid, apparently unrelated to breakdown, had not previously been reported we photographed it during the evening of January 6, 1938. The left-hand picture in figure 24 shows the electrodes photographed with room lighting. The right-hand picture is an 11-minute exposure with the room darkened and an electric gradient of 557 kv peak per centimeter applied to the liquid. The high lights were caused by street lights and were largely eliminated in succeeding

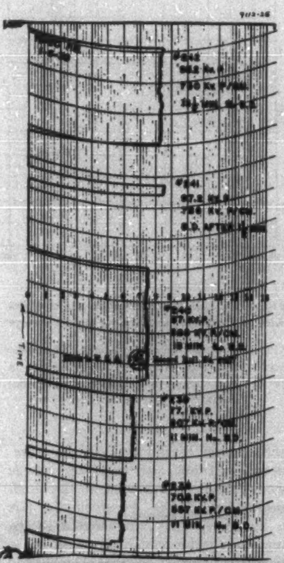

Figure 26. Primary voltage record obtained while photographing electroluminescence

photographs by using a black curtain between the cell and the windows. The right-hand picture in figure 24 shows a breakdown which occurred after about $1^1/_2$ minutes at 766 kv peak per centimeter. After this breakdown the liquid was allowed to circulate about six minutes and then 750 kv peak per centimeter was applied and held without breakdown for $15^1/_2$ minutes while the glow was photographed as shown. The voltage records for these photographs are indicated by "x" marks on the extreme right of figure 23 to show the order of magnitude compared to previous breakdown measurements with the same setup. Also the photoelectric primary voltage record obtained while these pictures were being taken is reproduced in figure 26.

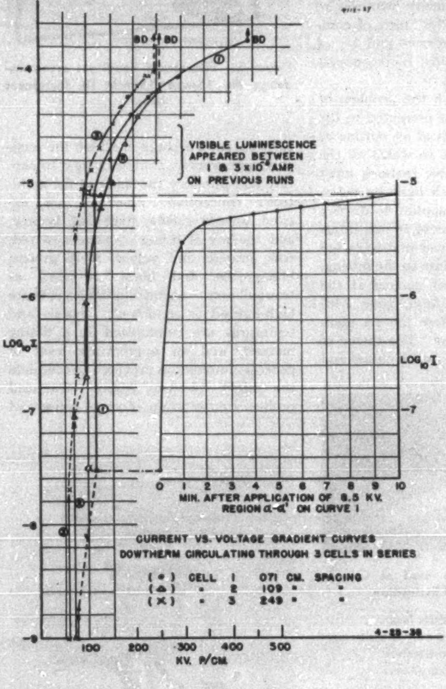

Figure 27. Current versus voltage-gradient curves in Dowtherm

CURRENT VERSUS VOLTAGE-GRADIENT RELATIONS

It seems to the writer that a very important tool in the study of the mechanism of breakdown in liquids is the examination of voltage-current relations.[13] Three typical curves are shown in figure 27 illustrating several interesting observations. Instruments were not available for current measurement below 10^{-9} ampere so that the initial Ohm's law current caused by the residual free ions in the liquid could not be measured. The low end of the current which we did observe was usually very unstable as though the instrument, which has a long time constant, was integrating irregular bursts of current of very short duration. The vertical lines terminated by arrow heads indicate gradual increases in average current observed while the voltage was held sensibly constant (that is, no change in regulator setting). The line $a-a'$ on curve 1 with its corresponding time relation to the right shows a 200/1 change in ten minutes, most of which occurred in the first minute. Data taken with a current instrument having a much shorter time constant would be necessary to resolve and interpret this rather crude observation.

The second interesting point is that under optimum conditions the electroluminescence threshold occurred regularly in a narrow range of current (1 to 3×10^{-5} ampere).

Another observation is the saturation effect at higher gradients with breakdown occurring unpredictably and without observable increase in current preceding breakdown within the time limit of response of our instrument. Although the experimental difficulties appear great, we hope to make some cathode-ray oscillographic studies of these currents.

Conclusions

1. In a filtered, water free, insulating liquid on which the hydraulic pressure is one atmosphere plus the partial pressure of gas in solution, the dielectric strength is unaffected by the partial pressure of air or CCl_2F_2 in solution from 0.01 micron to one atmosphere pressure.

2. The large average deviations observed even after days of continuous circulation, drying, filtering, and degasification support the conclusion of several previous experimenters that the condition of the electrode surface is a major controlling factor.

3. In one of the insulating liquids studied a diffuse glow, which occurred at gradients well below breakdown, was observed and photographed. To the best knowledge of the writer this phenomenon has not been previously reported. A descriptive name of "electroluminescence" is suggested since the cause appears to be electronic. The glow was completely quenched by admitting a few centimeters partial pressure of air or CCl_2F_2. The breakdown gradient was unaffected by the presence or absence of the glow.

4. Commercial insulating liquids treated under laboratory conditions and carefully freed from water and suspended solids have dielectric strengths of the order of 10^6 volts per centimeter, comparable to pure chemicals. This observation is subject to the reservation that the important factor in breakdown may be the condition of the electrode surface and its ability to emit electrons and not a specific property of the liquid.

Painting the Golden Gate International Exposition With Light

A. F. DICKERSON
NONMEMBER AIEE

H. E. MAHAN
ASSOCIATE AIEE

ON a man-made island of 400 acres which President Roosevelt has referred to as our latest insular possession, architects, artists, and engineers have constructed a magic walled city about an architectural plan that combines the ancient designs of Burmese, Cambodian, Incan, Mayan, and other Pacific cultures into the unique and surprisingly beautiful Golden Gate International Exposition. One and a half million dollars spent on landscaping and another million dollars worth of sculptures, murals, and decorations have made of it a "Garden of Paradise" and a comprehensive artistic architectural unit rather than a disconnected assemblage of exhibit buildings.

To design the lighting for such a composition requires that the engineer approach his problem with tolerance toward the view of others. The lighting must be in harmony with the work of the architects, artists, sculptors, and horticulturists, and strictly engineering considerations subordinated in many instances to those of aesthetics. This spirit of compromise between the science and art of illumination will be noted in the effects described in this paper.

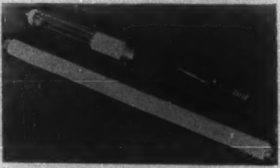

Figure 1. Light sources used at Golden Gate International Exposition

B—100-watt type *H*4 red-purple-bulb mercury lamp for fluorescence
C—250-watt type *H*2 mercury lamp

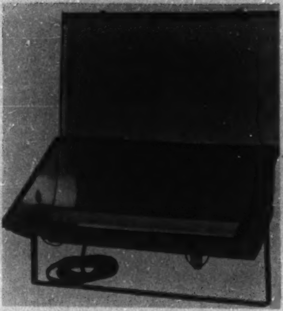

Figure 2. Fluorescent floodlight accommodating the 15-watt 18-inch T8 fluorescent lamp

The manner in which the problem of lighting an exposition is presented to the engineer takes the form of an outline of the architectural theme to which all the structural and decorative features must be related and in which light by color, direction, and scale is applied to display the architectural elements in an interesting and faithful manner and to create an atmosphere appropriate to the setting. The 12 principal exhibit palaces at the Exposition (see cartograph, page 746) serve to form and enclose the six main courts of the Exposition. The theme of each court is suggested by its name, and each becomes a stage in which the engineer endeavors by the use of light to capture and intensify the spirit of the architect's conception. Emotions are excited toward gaiety, liveliness, beauty, and the joy of living by shades of red, rose, orange, and yellow, while greens, blue-greens, and blues are used as tranquilizers. Architectural elements are high-lighted or shadowed; murals and sculptures are emphasized in a fitting manner, and an appropriate level of general illumination provided to complete the night picture. Many structural problems enter in an effort to house and

Figure 4. Sketches of lighting standards used throughout the grounds

conceal the lighting equipment and their solution requires the co-operative efforts of architect and engineer.

Since the introduction of the incandescent lamp in 1879 until the Panama-Pacific International Exposition in 1915, the decorative lighting of expositions took the form of outline lighting by strings of incandescent lamps. This exposition at San Francisco in 1915 marked the advent of floodlighting, although the equipment was improvised for the occasion and the commercial floodlight subsequently developed. The incandescent-lamp floodlight still assumes the major role in modern lighting because the incandescent lamp lends itself to dimming, color correction, and control of the light distribution. At the Golden Gate International Exposition the incandescent lamp is supplemented by three new light sources which make possible effects hitherto difficult to obtain. These light sources (figure 1) are the fluorescent lamp, the high-intensity mercury lamp, and the red-purple-bulb mercury lamp for obtaining ultraviolet radiation. Each has its distinct field of application.

C—Underwater fountain floodlights and Cel-o-glass-covered lip lights

D—Mercury ground floodlight for tree lighting

The fluorescent lamp is essentially a mercury arc generating ultraviolet radiation which is converted into visible light by the fluorescing of powders (phosphors) coated on the inside of the glass tube. The lamp used throughout the Exposition is 18 inches long and one inch in diameter, and available in seven colors. The lamp is housed in a trough-shaped floodlight (figure 2) having a double-parabolic section. The unit consumes 20 watts including the starting accessories and has an efficiency range depending upon the color produced. The fluorescent floodlight is used in various color combinations for illuminating building walls, setbacks, etc. (figures 5*A* and 6*C*) and has proved to be an invaluable tool for creating lighting effects.

The high-intensity mercury lamp in use is the 250-watt size housed in an Alzak-processed aluminum floodlight and the floodlight together with a transformer (figure 3) placed within a cylindrical-shaped container (figure 5*D*) buried in the ground. Concealed beneath trees and shrubbery these units serve to illuminate the planting with a moonlight quality of light and preserve for the night the charm of the landscaping at this unusual exposition.

The 100-watt red-purple-bulb mercury lamp for ultraviolet radiation is used for fluorescence excitation. It consists of a mercury arc contained within a filter-glass bulb which selectively absorbs the undesired radiation and transmits the near ultraviolet. This lamp is used in an Alzak-processed aluminum floodlight as a source of ultraviolet radiation for special features referred to later in this paper.

The exterior lighting of the buildings and courts is all done by the three types of light sources mentioned above together with standard types of incandescent lamps in a wide range of sizes, bulb and filament forms, and colors.

The west facade (figure 7) is the view one obtains from the San Francisco shore. The main wall and two setbacks are illuminated at increasing levels of illumination in the order of their occurrence from the ground. This preserves the architectural breaks as viewed from a distance. This lighting is accomplished by Alzak-treated aluminum floodlights with asymmetric door glasses and incandescent lamps. At the ground level the flood lights are installed in trenches provided for the purpose and completely concealed by trees and shrubbery. The floodlights illuminating the setbacks (figure 6*D*) are installed behind the parapets. Lighting equivalent to 1, 1.5, and 1.75 watts per square foot of wall surface is provided on the main wall, first setback, and second setback respectively. This general scheme is followed throughout for illuminating the outside walls of the exhibit palaces. The walls are finished with gypsum plaster of a light ivory color and a luminous luster is imparted to them by pressing into the plaster surface a mica product.

The elephant towers flanking the Northwest passage leading to the Court of Pacifica and the Portals of the Pacific leading to the Court of Honor are given emphasis by higher illumination levels relative to the building facades. Clear light provided by incandescent floodlights and searchlights is used for the general floodlighting of the pyramidal bases and formal elephants with red and ruby relief lighting along the steps and howdahs

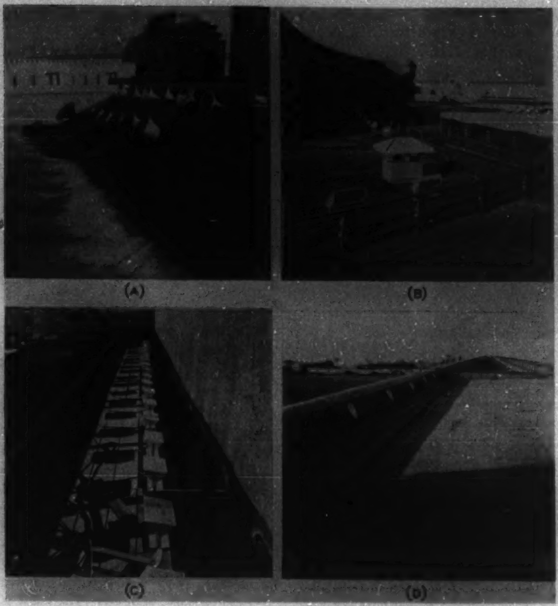

Figure 6

A—Bank of floodlights and searchlights for Tower of the Sun

B—Fluorescent floodlights on setback of Court of Honor

C—Fluorescent floodlights on setback of Court of the Moon

D—Floodlights for setback on west facade

to suggest the oriental theme of the setting.

The Court of Pacifica (figure 8) in design and location invited unusually striking lighting treatment tending toward the spectacular. Visitors pass through this court on their way to the Gayway or amusement section and it appeared fitting to prepare them psychologically for the bizarre effects to follow. The general illumination of the court is that of a warm glow emanating from cylindrical lanterns (figure 4*E*) 5 feet in diameter and 52 feet long, supported on a steel pole 86 feet high. The lanterns are formed of a Glyptal-treated fabric supported by a steel spider and contain incandescent lamps totaling 9,600 watts. Sixteen such standards or a total of 153.6 kw of general illumination are provided.

The great metal prayer curtain behind the 85-foot statue of Pacifica is silhouetted at night against a mat of mobile color consisting of amber, red, and blue light controlled by a thyratron reactor dimmer and passing through a cycle of changes. The lighted background is obtained by 13.6 kw of amber, 26.8 kw of red, and 52 kw of blue incandescent floodlights of 200 watts capacity each. Three 1,000-watt underwater floodlights in the pool at the foot of Pacifica illuminate the figure. The large sculptured and painted mural (figure 9) on the west face of the court symbolizing "The Peacemakers" is 144 feet by 58 feet and is illuminated by clear and amber light. Incandescent floodlights of 500 watts capacity and located at the base of the mural furnish the illumination totaling 12 kw of clear and 6 kw of amber light.

The cascades above which Pacifica is standing are illuminated by natural-green-bulb incandescent lamps behind Cel-o-glass risers. This lighting and the lip lighting on the central fountain is obtained by 60-watt lamps on six-inch centers. The large center bubble in the fountain is illuminated in mobile color controlled by thyratron reactor dimmers. A group of nine blue, four red, and three amber underwater floodlights of 1,500 watts capacity each provide the lighting effects. The larger trees are illuminated

Figure 7. West facade

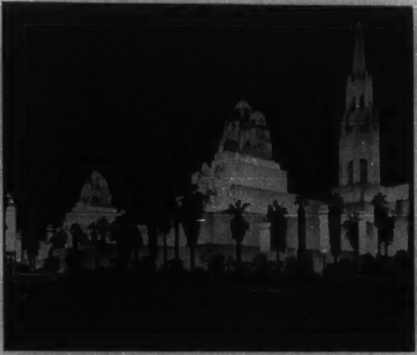

Figure 8. Court of Pacifica

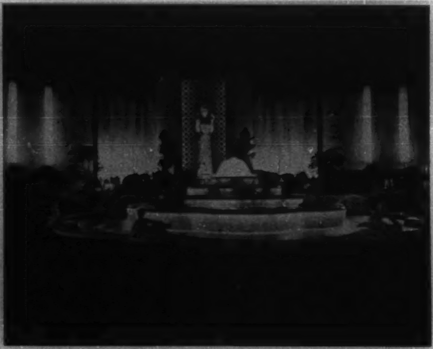

Figure 9. Court of Pacifica (mural "The Peacemakers")

Figure 10. Court of the Seven Seas and Tower of the Sun

by the mercury tree-lighting units referred to earlier in this paper and make interesting spots of contrast with the warmer tones in the court.

The walls flanking the grand stairs and also the walls of the east entrance are floodlighted in a golden amber tone by incandescent floodlights. The east entrance and Gayway plaza are lighted by decorative standards (figure 4*K*) with tiers of ivory lamps and banners, and serve as an introduction to the Gayway lighting (figure 4*L*). The total connected lighting load in this court is approximately 450 kw.

The Court of the Seven Seas (figures 10 and 11) is the longest court at the Exposition, measuring 1,000 feet by 200 feet and has a connected lighting load of approximately 225 kw. The lighting standards (figure 4*H*) provide the general illumination for the walks and are patterned in the marine spirit of the court symbolizing a ship's mast with the crow's nest housing the lighting equipment. This equipment for the "down" lighting consists of three 200-watt silvered-bowl lamps in open louvered reflectors. The "crows nest" is covered with Cel-o-glass and made luminous by transmitted light from four 75-watt inside-frosted incandescent lamps. The blue and white "sails" are floodlighted by means of eight 150-watt units concealed in the base. A spotlight concealed in the "rigging" is directed on the ship prows surmounting the facade piers between each pair of masts, giving prominence to these elements in the night picture. The lighting of the walls demonstrates the adaptability of the fluorescent floodlight for creating tints. A green apricot hue is obtained by mixing two 100-watt amber incandescent floodlights with one green and two pink fluorescent floodlights for each 12 linear feet. The main wall is 42 feet high and the castellated setback wall above it is illuminated by gold fluorescent tubes on the basis of approximately 0.2 watt per square foot of wall surface.

A very interesting effect is obtained in this court by the use of luminescent paints excited by ultraviolet-radiation sources. This feature occurs in the 16 niches depicting submarine life in bas-relief and represents considerable research work on the part of the manufacturers of luminescent paints in developing a product that would withstand the ravages of dust, sun, etc. The paint is applied to the bas-relief and activated by 16 100-watt red-purple-bulb ultraviolet lamps in Alzak-treated aluminum reflectors concealed at the base of each niche. A happy note is introduced by the use of 160 Glyptal-treated cloth lanterns suspended at random through the trees in the court and each equipped with a 25-watt inside-frosted incandescent lamp.

The Court of Honor is the focal point of the main group of Exposition build-

Figure 11. Details, Court of Seven Seas

Figure 12. Court of Reflections and Arch of Triumph

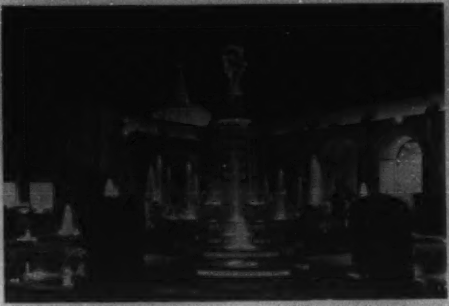

Figure 13. Court of Flowers

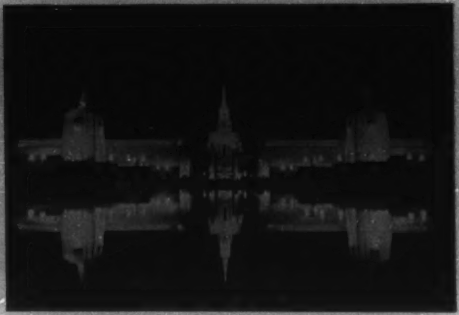

Figure 14. Temple Compound

ings and has as its central feature the Tower of the Sun rising to a height of 400 feet. At night the tower rises from a warm amber glow at the base to a brilliant white at the Phoenix surmounting the tower. The transition from amber to clear light is a very gradual one and scarcely discernible by reason of the blue and amber relief lighting at the openings at the several levels of the tower. A total of 450 kw of incandescent searchlights and floodlights (figure 6*A*) furnishes the lighting for the tower and the reflected light provides the general illumination for the court and flanking facades. Supplementary lighting takes the form of lighting standards (figure 4*G*2) equipped with single-light luminaires of 500 watts capacity each. Contrasting with the classical architecture of this court are illuminated trees, flags, and fountains.

The Court of Reflections (figure 12) adjoins the Court of Honor on the east and, as becomes a vantage point for observing reflections, the environment is one of placid quietness. From the east end of the reflecting basin one observes the reflection of the Tower of the Sun and from the west end the Triumphal Arch is mirrored in the pool. The Triumphal Arch is 107 feet in height and is floodlighted by means of incandescent floodlights and searchlights totaling 25 kw. The coral-colored walls of the court are lighted by pink fluorescent floodlights spaced on 4-foot centers, $3^{1}/_{2}$ feet from the base of the walls in trenches built for this purpose. The lighting standards (figure 4*I*) furnishing the general illumination of the court flank the reflecting pools and simulate Siamese ceremonial umbrellas. In design and scale they form a definite architectural element in the decorating scheme of the court. Each of the 20 standards is 53 feet high and has five tiers of painted-fabric shades assembled on a tapered steel pole. Incandescent lamps totaling 1,740 watts are installed in each standard. Recessed plaques illuminated by a blue fluorescent tube concealed at its base make interesting breaks in the large expanse of wall area. The total connected lighting load of the court is approximately 65 kw.

The Court of Flowers (figure 13) reflects the cheerful but restful mood that accompanies the play of fountains in a garden. The placid nature of this court provided the keynote for the lighting. The jets of the five fountains are all illuminated with clear light by means of underwater floodlights and the cascades emanating from the central fountain are illuminated in blue-green. The cascade lighting consists of incandescent lamps placed behind Cel-o-glass risers under the lip of the steps forming the cascade. Natural-colored-glass lamps of 40-watt size and spaced on six-inch centers were used throughout the exposition for this purpose. The equipment used for illuminating the jets comprised 68 250-watt cast-aluminum underwater floodlights and 8 1,000-watt units of the same type. These floodlights and others similarly installed throughout the Exposition are held in position by bolting them to a block of concrete resting on the basin floor as shown in process of installation in figure 5*C*. A lighted border of flowers completely encircles the fountain.

Similar standards (figure 4*J*) to the Siamese ceremonial umbrellas installed in the adjacent Court of Reflections provide the general illumination in this court and add a colorful contrast with the green foliage. The rear wall of the loggia surrounding the court is lighted in a warm tone by 60-watt pink Lumiline lamps arranged in luminaires made up of groups of 18 lamps each and spaced on approximately 30-foot centers. Light boxes containing three 150-watt incandescent floodlights illuminate the murals. The setback above the arcade is illuminated with pink fluorescent lamps on approximately five-foot centers. Occasional trees and shrubs are illuminated by mercury tree-lighting units and the green foliage silhouetted against the relatively darker piers and arches create interesting and ever-changing patterns.

The East Facade is lighted in clear light in much the same manner as the West Facade. Trenches of 6-foot width, completely concealed by shrubs and trees, house 500-watt asymmetric floodlights on eight-foot centers for lighting the 40-foot walls. The shrubbery brilliantly silhouetted against the wall, forms a pleasing break from the regularity of the facades. The illumination of the 14-foot setback is provided by 200-watt incandescent floodlights on 10-foot centers. This lighting is broken by large standards of a unique design at the building entrances and the beautiful East Towers and murals which form the east entrance to the walled city.

The East Towers (figure 14) rising from tiers of circular steps, are heavily ornamented in gold leaf and carried in golden light at night. The huge bas-relief gold-leafed murals are lighted by pink fluorescent and 150-watt amber incandescent floodlights concealed at their bases, and pink fluorescent floodlights light the setbacks. The terraces and stairs are lighted by Siamese umbrella-type standards (figure 4*P*) built of fabric and equipped with incandescent lamps totaling 2.4 kw per standard. This complete lighting picture is perfectly reflected as a gigantic panorama in the adjoining lagoon.

Figure 15. Fountain of Evening Star

Figure 16. Treasure Garden and Court of the Moon

The charm of the Court of the Moon (figures 15 and 16) with its decorations recalling the stories of Aladdin is carried into the night by a moonlighting effect relieved by high lights of amber from grilles, turrets, fountains, and lighting standards. The walls and towers of this court are illuminated by a total of 530 500-watt incandescent floodlights equipped with asymmetric blue lenses and 452 blue fluorescent floodlights mixed to obtain a blue-orchid-tinted tone. The 500-watt incandescent units are spaced on approximately 30-inch centers and the fluorescent units on approximately five-feet centers (figure 5*A*). In each of the half-cylinder reveals (16 feet diameter, 12 feet high) three blue fluorescent floodlights are installed and the top setback is similarly illuminated (figure 6*C*) in blue by fluorescent floodlights on approximately three-foot centers. A striking mottled effect is obtained on the tops of the towers by a mixture of blue and pink fluorescent floodlights.

The general illumination of the walks is accomplished by standards (figure 4*H*) equipped with two 300-watt silvered-bowl incandescent lamps in reflectors for down lighting and ten 60-watt incandescent lamps for illuminating the lantern. The lantern consists of an iron frame with Cel-o-glass covering and is mounted on a tapered steel pole 28 feet long. Ten of these standards are installed in the court.

Twenty-four jets of water emanating from both sides of the central lagoon form 12 water arches over the pool and are illuminated in an amber tone by 72 underwater floodlights of 400 watts capacity each. Statuary is spot lighted by incandescent projector lamps and trees are illuminated in the manner referred to elsewhere in this paper. The court has a total connected lighting load of approximately 425 kw.

Treasure Garden (figure 16) lies to the south of the Court of the Moon and in general treatment parallels the latter court. The central feature is an illuminated fountain consisting of a 60-foot center jet surrounded by eight 20-foot jets. The water is illuminated with clear light delivered from underwater incandescent floodlights grouped at the base of the jets. There are five 1,500-watt units at the center jet and three 400-watt units at each of the small jets, making a total of 17.1 kw for the fountain.

The basin wall is illuminated in green by 60-watt incandescent lamps concealed in a lip formed at the top of the wall and arranged in double sockets on 16-inch centers. The reflected light from these walls serves to illuminate the flower bed and walk surrounding the pool.

The four corner groups of trees are illuminated from mercury tree-lighting units and by reflection shed a moonlight quality of general illumination over the garden. Fabric lanterns distributed throughout the trees add cheerful spots of amber color to the scene.

A festive note is introduced into the general lighting of the amusement section by a star standard (figure 4*L*) using exposed inside-frosted incandescent lamps in the center and behind Cel-o-glass at the points. A total of 106 40-watt lamps and 10 150-watt lamps is used in each standard. The standards are 35 feet high and spaced 100 feet apart along the center of the walk.

A battery of 24 36-inch medium-intensity searchlights located on the north side of Yerba Buena Island and centered on the north-south axis of the Exposition, furnishes light for purely spectacular purposes. This searchlight operates at 125 amperes direct current with 65 volts at the arc and produces a beam of 60,000,000 candle power. The entire battery is maneuvered on special occasions by soldiers from the 30th Infantry, United States Army, and drills consisting of moving the beams in cadence or directing them on smoke shells and fireworks create a variety of spectacular effects. Each light is equipped with gelatin screens for color changes. When not manned for drills the battery is spread out as a fan in clear light or color to form a light canopy over the Exposition site.

The utilitarian lighting for the roadways was designed to provide adequate visibility for pedestrians with a minimum of conflict with the decorative lighting. Series circuits independent of the general electrical distribution system were chosen for convenience of control and economy of installation. All of the series luminaires used throughout the grounds are equipped with 6.6-ampere 6,000-lumen lamps. The general lighting of roads and walks is done with a tubular steel pole supporting a pendent luminaire (figure 4*M*) with rippled alabaster-glass globe. Standards are located on both sides of the road with an average spacing of 120 feet between standards. The plaza at the entrance to the administration building is illuminated by an upright luminaire (figure 4*D*) equipped with a polycase glass cylinder. In order to avoid interference to observers approaching the island by ferry boats, it was essential to employ light sources along the high-speed service roads on the western water front, that had a cutoff below the horizontal. The luminaire and standard (figure 4*C*) installed for lighting these roads is a pendent type consisting of a stepped Alzak aluminum reflector and spun-on refractor globe. The standards are spaced 150 feet apart on both sides of the road.

The automobile approach to the Exposition from the San Francisco-Oakland Bay Bridge is illuminated by 10,000-lumen series sodium lamps of the type used on the bridge. These standards (figure 4X) are spaced approximately 150 feet apart on opposite sides of the roadway and have a height to light center of approximately 25 feet.

There are many exhibit buildings at this Exposition with lighting effects worthy of consideration in this paper but which are omitted because of space limitations. Also there are many of the lighting features referred to which appear to be hastily dismissed with an inadequate description of the technical details. Several reasons prompt the authors to do this. Decorative lighting as was mentioned at the opening of this paper is more of an art than a science and considerable nonuniformity exists in the actual placing of the light sources to obtain the effects desired. Also, parallel architectural conditions seldom occur in practice. Consequently attempts to state the conditions of the problem and the method finally adopted to solve it are both involved and of little value as a guide.

Power is delivered to the Exposition at 12 kv by three 500,000-circular-mil three-conductor cables from Oakland and San Francisco to a 16,000-kva substation situated at the south side of the Palace of Fine Arts. This power is transformed from three-phase delta to 2,300/4,000-volt three-phase four-wire and distributed by 15 circuits to approximately 35 transformer substations throughout the grounds. An auxiliary substation of 4,000-kva capacity located at the amusement section serves this section. The secondary distribution for decorative and general lighting is four-wire 208-120 volts.

The series street-lighting circuits are ten in number; four originating from the substation and the remainder cascaded from them. These circuits operate at 6.6 amperes regulated by constant-current transformers. The total connected load fed from these series circuits is approximately 225 kw. The total connected load for the exterior lighting exclusive of the street lighting is approximately 4,000 kw. The battery of searchlights on Yerba Buena Island requires approximately 450 kw.

COLOR: NEW SYNTHESIS IN THE WEST

PLATE 2. One of the most dramatic aspects of the Golden Gate International Exposition (seen here from Yerba Buena Island) is the clear integration of the exterior illumination system with the architectural design. Note the careful organization of both colors and intensities, the visual sequences achieved thereby, the subdued and largely decorative role of street lighting.

COLOR, LIGHT AND STRUCTURE AT GOLDEN GATE EXPOSITION

Almost unnoticed, the rapid development of new illuminants and lighting equipments has, in the recent past, added a distinct and prodigious dimension to the field of exterior illumination—that of color. But precisely because the application of color to buildings is both a complex and unevenly explored field, available examples are few and often inconclusive. A notable exception is this year's Golden Gate International Exposition. Here—with a scale and completeness seldom approached before—is an artificial illumination system which is an integral part of the project design. Mr. Dickerson's paper thus not only describes an illumination project of interest to light specialists but constitutes reference material of prime value to building designers, engineers, and others. All photographs were specially taken by Gabriel Moulin for ARCHITECTURAL RECORD.

by A. F. DICKERSON,
*Director of Illumination**

EACH OF THE great American expositions has marked progressive advances in the field of artificial illumination. Chicago's Columbian Exposition of 1893 startled the world with its wide use of the then-novel incandescent lamp. In 1915 the Panama-Pacific Exposition in San Francisco reached new levels in the use of exterior floodlighting. Chicago's Century of Progress showed further advances, particularly in the field of color. But it is safe to say that the current expositions employ a wider variety of new illuminants, equipments, and installations than all their predecessors combined. The Golden Gate International Exposition furnishes dramatic proof of such advances; and because the problems involved are applicable to all building design, description of its principal features seems worthwhile.

Daylight color: A standard palette of 19 colors and gold was adopted—with ivory, brown, gold and blues predominating. Seven colors are body or foundation colors; eight are used for embellishment of minor architectural features, four and gold for trim. Tints and shades, rather than pure colors, are employed throughout. All body colors are warm, with light intensities — yellow, ivory, fawn, ecru, taupe, brown, and blue; the secondary colors include yellow, jade (light and dark), emerald, four additional blues, red, mauve, and apricot.

In the majority of cases, this color was applied in pigment form in the plastered surfaces, in paint form on trim and detail. The plaster itself has an unusual luminosity, an effect achieved by pressing a mica product into plastered surfaces. The mica had first been heated to a high degree so that it became flaky and the laminations tended to separate. The result is a breaking up of the wall surfaces into innumerable small holes with a high reflective factor.

Night color: The artificial illumination must be understood as being superimposed on a base of the colors and surfaces described above. But the night color *does not seek to reproduce that of natural daylight.* On the contrary, many of the most successful effects are achieved solely with colored illumination on near-white surfaces. Compare, for example, the daylight and night colors of the Court of Pacifica (Pl. 3 and 4). Nor do the various *intensities, shadows, and silhouettes seek to duplicate those of natural daylight.* In fact, the illumination may be said to yield an additional —and entirely new—design over and above that of daylight.

The basic consideration in designing the illumination of the Exposition was to make it a truly integral part of the building design. Such integration of light and structure implied much more than mere concealment of the light sources, or avoidance of glare and shadows. That it has been achieved —and with spectacular success in installations such as that of the Court of the Moon (Pl. 9) and the Elephant Towers (Pl. 5)—is apparent. Here color achieves a luminosity which appears as coming from *within* the building rather than of being applied from *without.*

Once inside the bright exterior walls, the visitor moves through a series of color effects in a succession of walled courts—each lighted differently, with a harmony which makes the transition from one to another easy, yet distinct. In these courts, lighting has been used to fit the visitor psychologically to enjoy the setting. Emotions are excited toward gaiety by shades of red, rose, orange, and yellow— while greens, blue greens, and blues are used as tranquilizers. Colors are always in harmony and restricted in number from any viewpoint. Highlights, shadows, and silhouettes break up the monotony of the usual flatness of floodlighted surfaces. Advantage has been taken of every flag, niche, or unusual architectural element, to introduce a change of color or a highlight in order to increase the liveliness of the night scenes. Fountains throughout the grounds are illuminated, usually in static colors excepting in the Court of Pacifica (Pl. 3) where a shifting color cycle is controlled by thyratrons. In many places trees have been lighted by concealed mercury floodlights; but in general they count as dark masses against light.

Installations and fixtures: While the effect of the Exposition's illumination system may often appear extravagant, construction and operation were in fact relatively simple and inexpensive. All equipment is commercially available, including a weather-proof low-cost searchlight and a low-cost fluorescent floodlight, both of which were especially developed by General Electric for the Exposition. The various installations are in common use in ordinary commercial buildings: *floodlighting*—in trenches, set-backs, soffits, etc.; *spotlighting* of architectural features —towers, sculpture, niches, etc.; *groundlighting* by means of light standards and recessed fixtures; *water lighting* by underwater floodlights, lip lighting, etc. The chief interest here lies largely in demonstrating the extraordinary versatility possible with careful study at a sufficiently early stage.

But each of these installation types represents a high degree of specialization so that, when properly integrated, there is little need for supplementary lighting. This explains the relative unimportance of street-lighting units in the illumination design. In the major courts, these units serve more as architectural features than as sources of illumination. Outside the courts, street-lighting units of a more utilitarian character are used.

Illuminants: The range of lighting media includes all commercially available sources — incandescent, lumiline, arc, mercury- and sodium-vapor, neon, fluorescent, and ultra violet "black light" for use with luminescent paints. These media were used singly and in combinations, depending upon the colors, changes, and intensities desired. Quantitatively the most important were incandescent and fluorescent lamps — the specially developed fluorescent floodlights being widely used.

All illumination designs shown are by General Electric's Illuminating Laboratory.

---

*The overall design of day-and-night color is the end product of close cooperation between the following Exposition officials: W. P. Day, Director of Works; Jesse E. Stanton, Director of Color; Edward L. Frick, Chief of Division of Architecture; William R. Van Bokkelen, Chief of the Electrical Division; George E. Garthorne, Assistant Chief and in charge of Exterior Illuminations; the entire Architectural Commission under the chairmanship of Arthur Brown, Jr.; and Mr. Dickerson, Director of Illumination.

No novice in the field, Mr. Dickerson played an important part in the illumination of the Panama-Pacific Exposition of 1915, the Brazilian Centennial in 1922, A Century of Progress in 1933, and in floodlighting of Niagara Falls. Since 1932, he has been head, Illuminating Laboratory and Lighting Sales of the General Electric Company at Schenectady, N. Y.

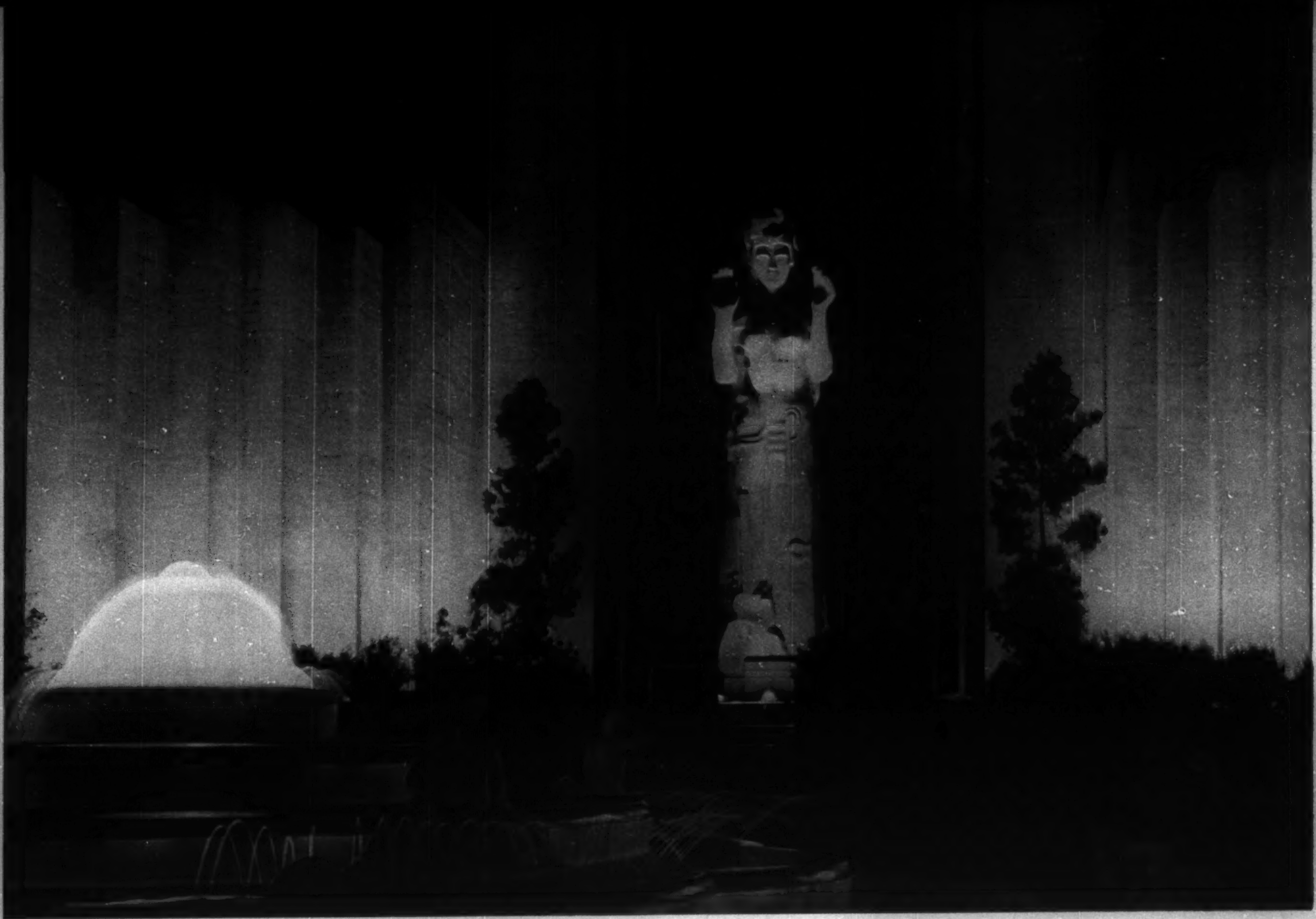

PLATE 3. Vivacity is here achieved not only by a wide variation of color and intensity of light but also by its movement. Synchronized thyratron controls give smoothly changing yet steady emphasis to the two most important architectural features—the statue and the fountain. Backgrounds have even values and harmonized colors which silhouette the planting.

THE COURT OF PACIFICA

TIMOTHY L. PFLUEGER, Architect

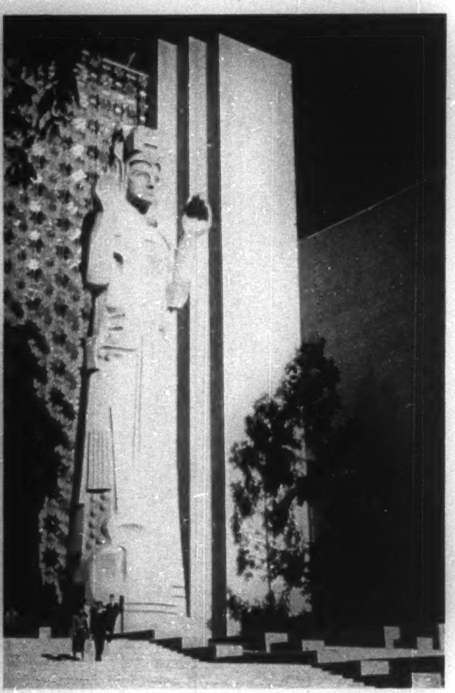

PLATE 4. This daylight view serves as a point of reference as regards the daylight-color base on which illumination is superimposed. All structures illustrated have similar colors and values.

FIGURE 3

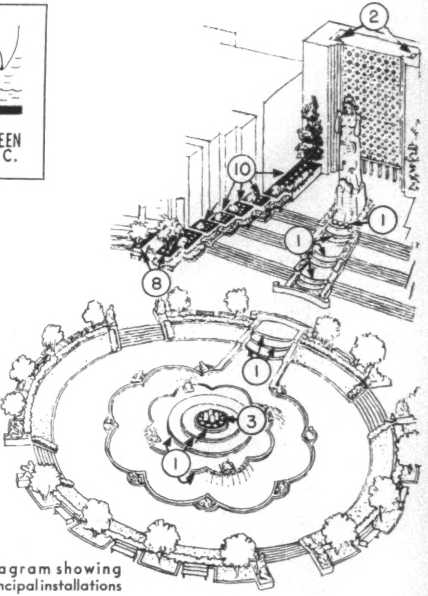

Diagram showing principal installations

THE DESIGN of this court, as well as its location adjacent to the most popular entrance to the Exposition, called for a lighting treatment tending toward the spectacular. The chief installations of the illuminating system are:

The Great Window with its stainless-steel screen and plaster backdrop lit by 75 amber, 150 red, and 300 blue 200-w. floods controlled by thyratrons. (Fig. 2);

Robert Stackpole's 85-ft. statue, "Miss Pacifica," lighted by two 1500-w. underwater floods (Fig. 1);

The cascades and central fountain, with lip lighting of green and changing colors from underwater floods where there are jets. (Figs. 1 and 3);

The 80-ft. walls flanking the Grand Stairs and also the walls of the East Entrance are flooded in a golden amber (similar to Fig. 10);

Sixteen 86-ft. cylindrical lanterns (not shown) of Glyptal-treated fabric shed a warm glow that completely envelopes the Court. Each lantern has three-hundred 60-w. lamps, or a total of 288 kws. is used for the 16 standards (design similar to Figs. 6 and 7);

All of the main trees are lighted with 250-w. mercury floods concealed in ground cylinders (Fig. 8);

The East Entrance and the Gayway Plaza are lighted by decorative units with tiers of amber-orange lamps and banners. This exposed lighting furnishes a transition to the Amusement Section. Approximately 550 kws. of lighting are used in this Court.

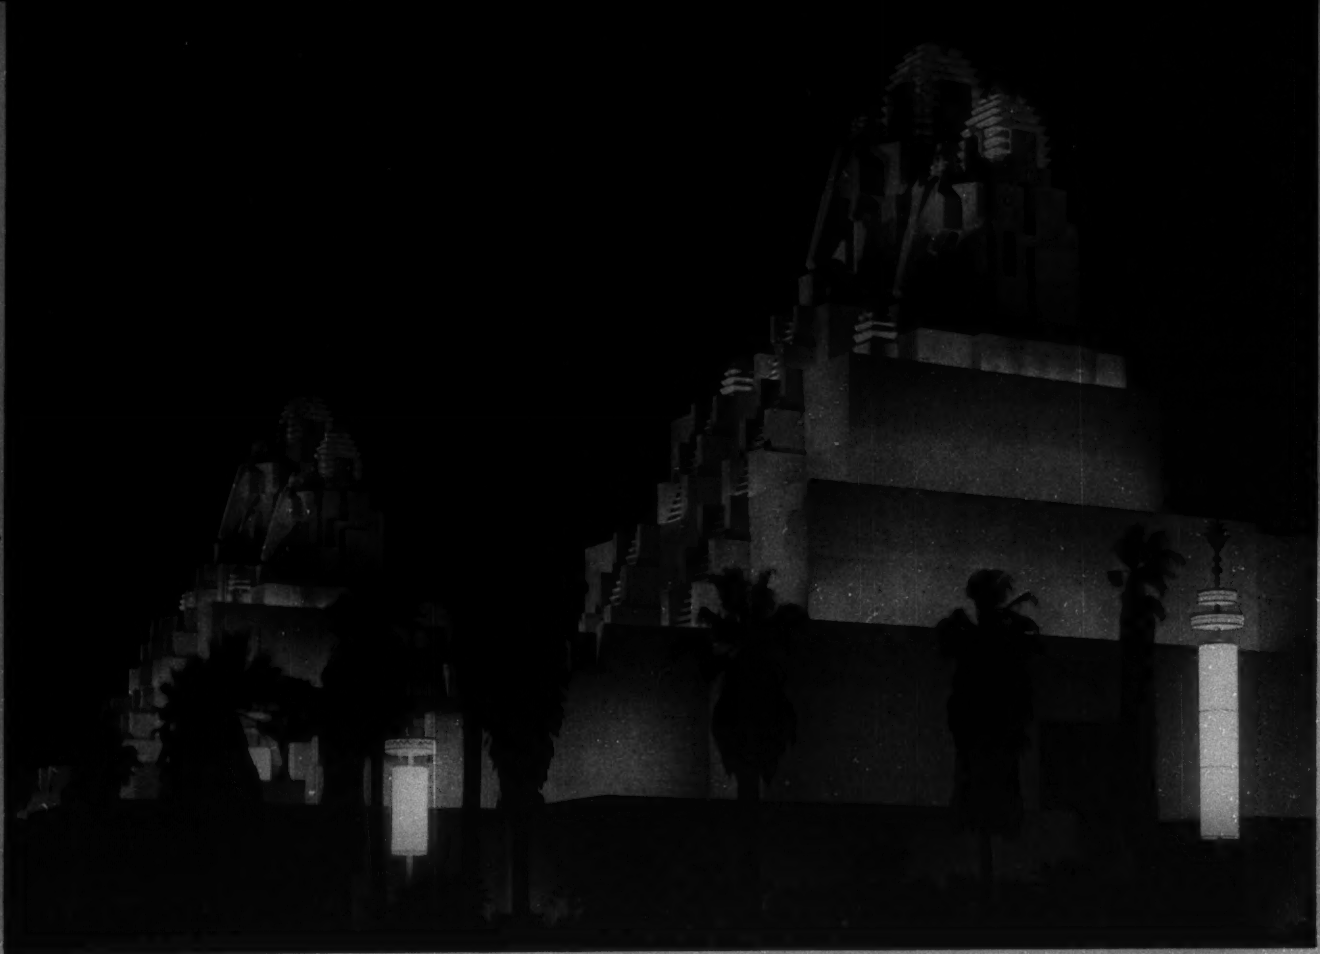

PLATE 5. Highest intensities and lightest colors have been widely used on those elements primarily designed to be seen from afar. Thus the brilliantly lit West Facade, with its monumental entrances, actually serves as a huge sign which dominates the city's eastern horizon and intersects its traffic lanes to the mainland. Colors are concentrated at the entrances.

THE ELEPHANT TOWERS AND WEST FACADE

ERNEST E. WEIHE, Architect

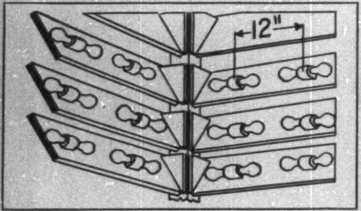

FIGURE 4

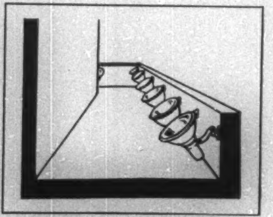

FIGURE 5

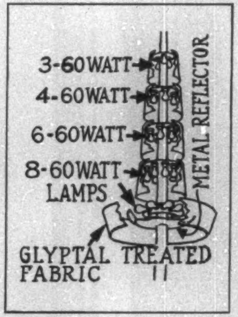

FIGURE 6

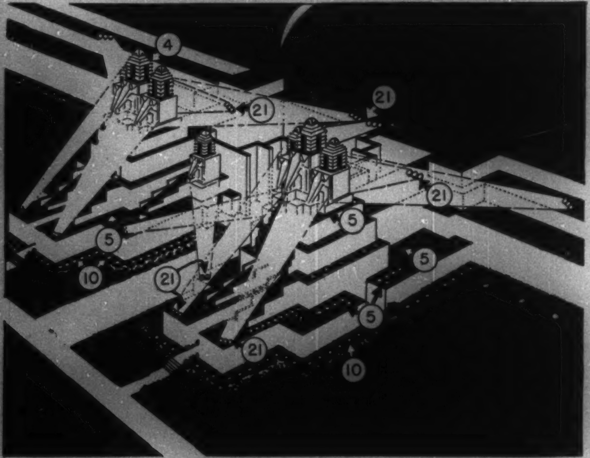

Diagram showing search- and floodlight locations for Towers and West Facade

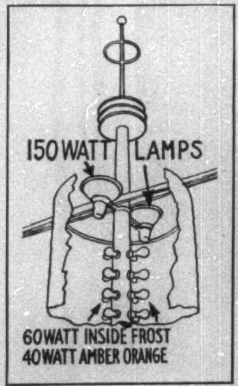

FIGURE 7

The West Facade, for its entire distance of 3600 ft. from the Administration Building north, is floodlighted in white with color reliefs at the South Tower, main Elephant Tower entrance, ferry entrance, and in the seven large green circles above the entrances. Thirty cylindrical lanterns, 50 ft. in height with 4920-w., and 102 similar small lanterns, 18-ft. high with 1620-w., add a festive note to this area. These lanterns are all steel framework on steel poles with decorated Glyptal-treated fabric as the transparency (Figs. 6 and 7).

The main wall is lighted by Novalux L-49 floods with polished Alzak-processed reflectors, asymmetric lenses and 500-w. I. F. MAZDA lamps. These are spaced on 10-ft. centers, 15 ft. from the base of the wall, in a specially provided trench that is completely concealed by trees and shrubbery. (Similar trenches of various widths are used for all floodlighting throughout the Exposition. See Fig. 10.) In general, illumination values increase with height (Pl. 5): on the first set-back 200-w. floods with etched reflectors and clear lenses are used on 8-ft. centers; 300-w. floods on 10-ft. centers light the second set-back (Fig. 5). The elephants themselves are picked up with 18-in. incandescent searchlights equipped with 1500-w. floodlighting lamps (Fig. 21). The louvered "howdahs" are in red, with 60-w. natural ruby incandescent lamps 12-in. o.c. (Fig. 4).

White light on the cream plaster yields surfaces whose values are approximately equal to those of daylight

PLATE 6. The richly textured golds of Lulu Braghetta's and Jaques Schnier's bas-reliefs are carried in pink, the towers in golden amber, while the set-backs are carried in lavender. Here, again, a brilliant lighting effect is adequately framed by quiet, unlighted water. Thus the scale and balance of daytime are maintained at night while new colors are introduced.

THE CAMBODIAN TOWERS AND EAST FACADE

WILLIAM G. MERCHANT, Architect

THE ENTIRE East Facade (to the right but not shown) is lighted in uncolored light in much the same manner as the West Facade. Trenches of 6-ft. width, completely concealed by shrubs and trees, house 500-w. asymmetric floods on 8-ft. centers for lighting walls (Fig. 10); the illumination of the set-back is provided by 200-w. floods. This lighting is broken by large standards at the building entrances and the East Towers and murals (Pl. 6) which form the East entrance to the walled city.

The Towers, rising from tiers of steps, are heavily ornamented in gold leaf and carried in golden light at night. The huge bas-relief gold-leafed murals are lighted by pink fluorescent floods concealed at their bases (Fig. 12), and similar installations light the set-backs in lavender. The terraces and stairs are lighted by Siamese umbrella-type units built of fabric. Trees in the center are floodlighted by 250-w. mercury-vapor lamps (Fig. 8). The lighting of flags and flag masts uses the same installation employed elsewhere (Fig. 9).

THE COURT OF REFLECTIONS
LOUIS P. HOBART, Architect

PLATE 7. Connecting the brilliant East Entrance (Pl. 6) and the Tower of the Sun (Pl. 11), the color and lighting levels of this court are adroitly handled. Walls and set-backs are lighted with pink fluorescent floods (Fig. 12), niches with blue fluorescent tubes (Fig. 22). The Arch is flooded from base and adjacent roofs with white 18-in. incandescent searchlights (Fig. 21).

Vol.
1940

PLATE 8. Looking west in the Court of Reflections towards the Tower of the Sun. As the name implies, water is here used as a reflecting medium to pick up and repeat the brilliantly lit Tower of the Sun. Elsewhere (Pls. 1, 10, and 11) water becomes part of the illumination system itself, adding not only color and movement but a considerable amount of light.

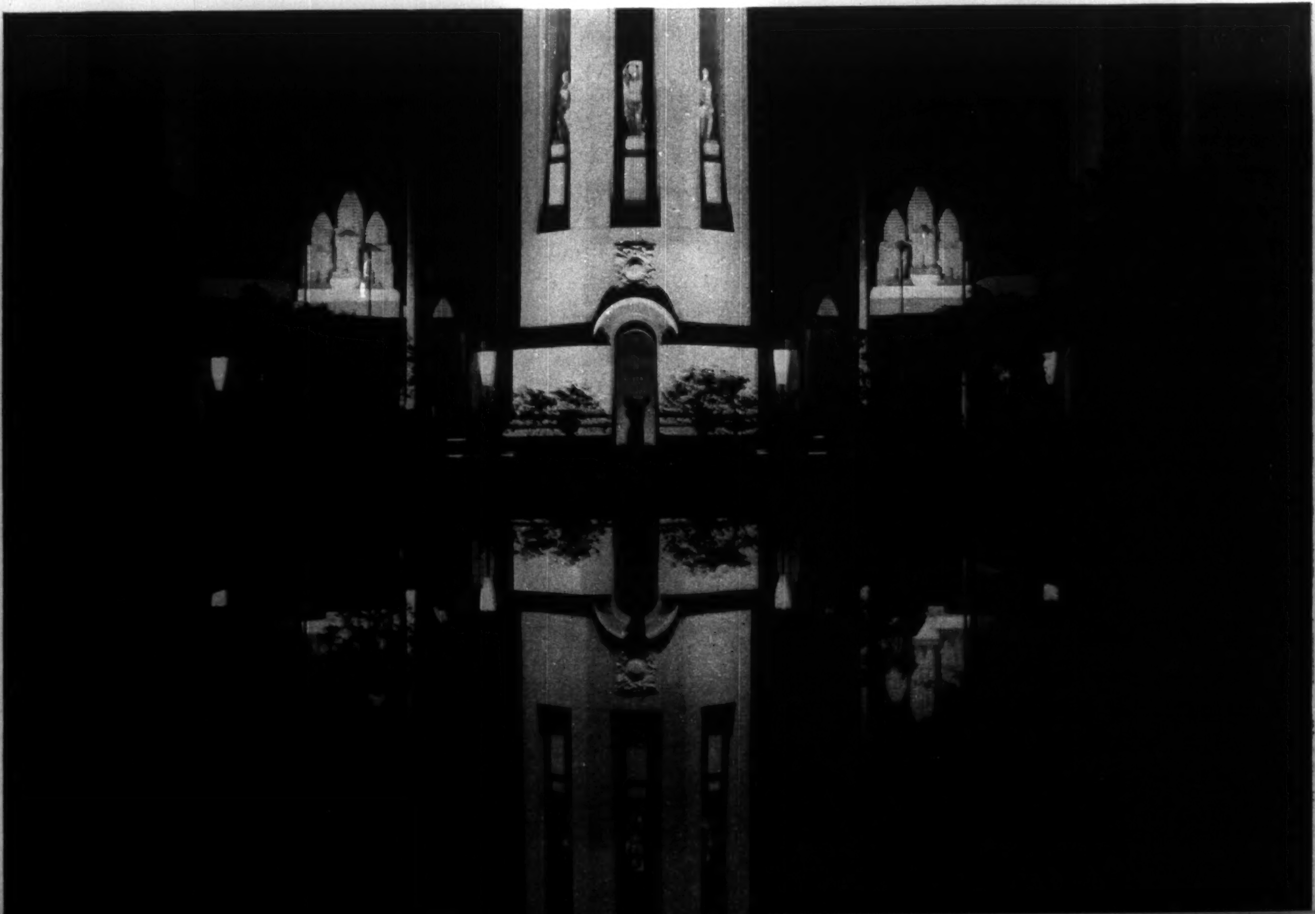

PLATE 9. Illumination of this Court is subdued, employing cool colors and low intensities. The main walls are carried in blue with a lavender overlay, while the set-backs are in blue; a mottled pink-and blue effect is used on the towers. All relief lighting—in grilles, niches, and louvers—is carried in amber to lighten the effect and tie it in with that of the other Courts.

THE COURT OF THE MOON

GEORGE W. KELHAM, Architect

HERE, AGAIN, illumination cannily implements both architecture and circulation: although physically one of the four major axes which radiate from the Tower of the Sun, this court is unimportant circulation-wise. The illumination is thus subdued, designed for relaxation, not for pulling heavy traffic. For the walls, 500-w. blue floods are used on 30-in. centers; in the same trench, pink fluorescent floods on 60-in. centers tint the blue to an orchid shade (Fig. 16). The crenelated set-backs are lighted with three 15-w. blue fluorescent floods (Fig. 15). Both blue and pink fluorescent floods are used on the tops of the towers for producing the striking mottled effect (Fig. 14).

Ground lighting is by downlights in ten units concealed in decorative elements of iron and Celoglas (Fig. 17). The other lighting features are: the 24 arches of water, lighted by seventy-two 250-w. amber underwater floods; the north fountain with its falling jets and cascades in amber (Fig. 13); mercury lighted trees; spotlighted statuary; grilles and turrets in amber relief lighting.

PLATE 10. The golden-amber floodlighting on both Cadorin's sculpture, "Evening Star" and the long pool save the lighting of the Court of the Moon from appearing too low or subdued in key — the 24 jets and the fountain itself give movement to the scene. Added color is achieved by the mercury-lit trees and the relief lighting in amber.

THE TOWER OF THE SUN

ARTHUR BROWN, JR., Architect

Since the Tower of the Sun is the "theme center" of the Exposition, and since the Court of Honor in which it stands is consequently the most important traffic intersection within the Exposition gates, it was important that the night effect be at least as dramatic as that of daytime. This has been accomplished (Pl. 11) by concentrating light at high intensities on the Tower, which in turn lights the Court by reflection. The shaft proper is lighted by 56 white 1500 w. searchlights (Fig. 21), 24 amber and 24 white 1000 w. floodlights, and 60 amber 1000 w. floodlights (Fig. 20). A ring of twenty-four 500 w. concealed street-lighting units (Fig. 23) supplements the court lighting. Other features are: the four illuminated fountains (Fig. 1), the eight flags (Fig. 9), the four belvederes and the lighted trees (Fig. 8).

The surrounding Court of Honor is mainly illuminated by this reflected light, although 24 decorative street lighting units supplement the design.

Ionization Time of Thyratrons

A. E. HARRISON
ASSOCIATE AIEE

Synopsis: Seventeen thyratron and grid-glow tubes, representing 12 different types, have been tested, and their ionization times have been measured with a cold-cathode-type oscillograph. These ionization times vary over a wide range, from a fraction of a microsecond to several hundred microseconds. Ionization time has been found empirically to be inversely proportional to grid overvoltage. Grid overvoltage is defined as the difference between the potential applied to the grid and the critical potential necessary to prevent firing. Argon, neon, and mercury-vapor tubes were included in the test. Mercury temperature was found to have no appreciable effect on the ionization time with low grid overvoltages. All mercury-vapor tubes have similar ionization-time characteristics. In fact, tubes of the same type and manufacture sometimes differed from each other more than one tube differed from another tube of different construction and manufacture.

GRID-CONTROLLED vapor-filled rectifiers, or thyratrons, have not been considered in the past for use in blocking and sweep circuits for cold-cathode-type oscillographs because of their inherent ionization time. A search of the literature on the subject, and reference to manufacturers' data sheets furnished little useful information on this ionization time. A research program to determine the minimum ionization times of various tubes was thus started in 1938, and first results showed that minimum ionization times of 0.3 microsecond were obtainable with mercury-vapor thyratrons if the grid was driven sufficiently positive. These results suggested that these tubes might be successfully used in blocking circuits for high-speed oscillographs, and work on this phase of the problem is being continued. The apparatus devised for measuring ionization times made possible an extended study of the relation between ionization time and grid overvoltage as a function of anode voltage and vapor temperature (for mercury tubes) and it is the results of this extension of the original problem which will be discussed.

Experimental Procedure

Ionization time of a thyratron, or the delay between the time of application of a square wave impulse to the grid and the time the tube voltage reaches its normal conducting value, is easily measured with a high-speed cathode-ray oscillograph arranged to record the voltage across the tube, provided that the time of application of the grid impulse is also shown. It is necessary to synchronize the unblocking of the high-speed oscillograph with the tripping impulse applied to the tube under test. (Tube *B* in figure 1.) This is accomplished by the use of a trip tube (tube *A*) which is fired by a surge from the oscillograph blocking circuit, delayed a fraction of a microsecond by R_5C_g. An impulse of magnitude determined by the ratio of $R_3/(R_3+R_4)$ is applied to the grid of the tube under test when tube *A* fires. Grid impulse voltages from 3 to 63 volts are selected with a tap switch connected to different values of R_3, allowing the grid overvoltage, or difference between the potential applied to the grid and the critical potential necessary to prevent firing, to be varied over a wide range. The time of application of grid impulse is recorded on the oscillogram through the coupling capacity C_4. C_4 and C_5 are small coupling capacities formed by one-inch lengths of twisted insulated wires.

R_1, R_6, R_7, R_8—1,000,000 ohms
R_2—20,000 ohms
R_3—50–1,350 ohms
R_4—3,700 ohms
R_5—100,000 ohms
C_1, C_2—1 microfarad
C_3—0.001 microfarad
C_4, C_5—Twisted wire capacities
C_G—Electrode capacity
Tube *A*—885 thyratron
Tube *B*—Tube under test

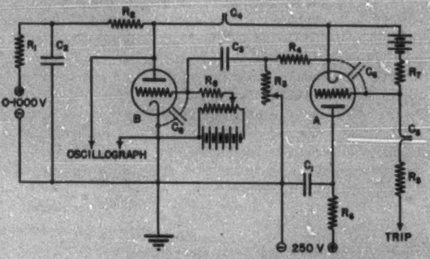

Figure 1. Circuit diagram of thyratron test apparatus

Values of grid impulse voltage were calculated from the ratios of $R_3/(R_3+R_4)$ for the various taps and were checked with the cathode-ray oscillograph. The apparatus was mounted as near the oscillograph as possible (see figure 2) in order to reduce the length of leads. Tests with the oscillograph verified that the time constant of R_4 and the grid-to-cathode capacity of tube *B* had no appreciable effect on the measurement of the ionization time.

First tests were made with the tube under test in a circuit similar to that of tube *A* without R_5, and ionization times were measured from the beginning of the oscillogram. Two factors made such a simple circuit unsatisfactory; there was no control of grid overvoltage independ-

* An 866 rectifier with a control electrode added. Manufacturer unknown.

ent of initial grid bias, and tests with an 885 indicated that the delay in the blocking circuit of the oscillograph was greater than the minimum ionization time of this tube. Both drawbacks were eliminated by the addition of a trip tube to the circuit. An 885 tube was finally chosen as a trip tube because its breakdown time was quite short and gave the best approach to a true square-wave impulse. R_5 was therefore added to delay the trip until the oscillograph sweep had started.

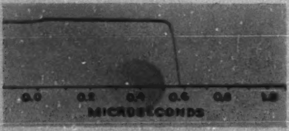

Figure 3. Typical oscillogram for an 885 thyratron

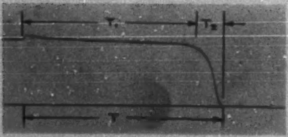

Figure 4. Different phases in breakdown of an FG-57

T_1—Time lag
T_2—Breakdown time
T —Ionization time

Direct coupling and capacitive coupling to the grid of tube *B* were tried and capacitive coupling was finally adopted because it allowed control of initial grid bias with a potentiometer and frequent check of the critical bias was possible. Originally, carbon resistors were used for R_3 and R_4; but this type of resistance has an odd behavior under transient conditions and the grid impulse voltage could not be calculated from the d-c resistance of the carbon units. Metallized resistor units for R_3 and ten metallized resistor units approximtely 400 ohms each in series for R_4 overcame this difficulty, giving a voltage divider with approximately the same characteristics for d-c and transient conditions.

Condensed-mercury temperatures were measured with a mercury thermometer wrapped with tinfoil and tied against the base of the bulb. This method did not give accurate measurement of the temperature, and did not allow tests at subnormal vapor temperatures, but the results do indicate qualitatively the effects of changes in mercury temperature.

Test data were obtained photographically for the 12 types of tubes listed in table I after the tubes had reached an equilibrium temperature. Three or more oscillograms were taken for each value of grid overvoltage and a fixed anode voltage. The sensitivity of the oscillograph was such that anode voltages greater than 1,000 volts could not be recorded easily. The time base was calibrated with a radio-frequency oscillator which was checked against broadcast stations. Figures 3 and 4 are representative oscillograms of anode-to-cathode potential. Ionization time is measured from the time of application of grid impulse, recorded as a slight rise in voltage at the beginning of the oscillogram, to the time at which the tube voltage has dropped to its conducting value. The ionization time for the Strobotron was an exception, since a Strobotron is used without a load resistance to discharge a capacitor, and its ionization time was measured to the beginning of breakdown.

Experimental Results

Ionization time as a function of grid overvoltage has been plotted in figure 5 for six of the tubes listed in table I. Inspection of the curves of figure 5 suggests a resemblance to a family of rectangular hyperbolas. Figure 6 was prepared to check this suggestion and shows the reciprocal of ionization time plotted as a function of grid overvoltage. The resulting curves are nearly linear, indicating that the hyperbolic form of the curves in figure 5 is not an illusion. The greatest deviation from linearity is shown by the *FG*-81; but this is not surprising since the maximum grid overvoltage is high compared with the anode voltage. All of the argon-filled tubes reached a low value of ionization time with a grid overvoltage of 20 or 30 volts, and further increase of grid impulse voltage failed to reduce the ionization time appreciably.

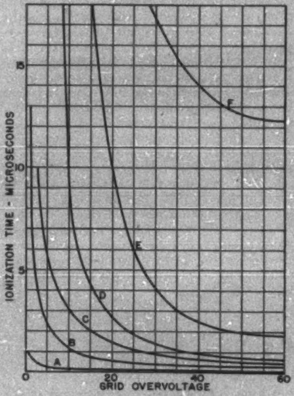

Figure 5. Typical ionization-time curves for thyratrons

A—885 argon-filled thyratron, 300 volts on anode
B—*FG*-81 argon-filled thyratron, 180 volts on anode

E—*KU*-610 neon-filled thyratron, 750 volts on anode
F—Strobotron, neon-filled, cold-cathode, 350 volts on anode

V. C. Rideout, graduate student at the California Institute who is continuing this study, has varied grid bias, grid impulse voltage, and anode voltage proportionately in an attempt to maintain proportional gradient values for each test. His conclusions are not yet definite, but there is reason to believe that this technique gives reciprocal curves which are more nearly linear.

Published data regarding the ionization times of thyratrons are meager. Hans Klemperer[1] in 1932 suggested a theory based on the mobility of the positive ions, and his calculated ionization times agreed in magnitude with his observations. Unfortunately the magnitude of the positive impulse applied to the grid by his method was not given, although it apparently was large. Klemperer's theory predicts that the time from the application of grid overvoltage until the start of voltage decrease across the tube, (T_1 in figure 4) and the time for the anode voltage to reach its final conducting value after decrease across the tube has begun, T_2, should be approximately equal. This relation is true for large grid overvoltages, but it is definitely not true for low grid overvoltages. The ionization time may depend on the initial number of electrons available to cause ionization, the so-called dark electron current.[4,6] Some vapor tubes have much larger dark electron currents just before breakdown than others. Figure 4 indicates the existence of a relatively large electron current by a gradual drop in anode voltage before final breakdown. No change in the ionization time of a *KY*-21 was observed when R_3 was changed from 20,000 ohms to 2,000 ohms if the grid overvoltage was greater than five volts. There is a substantial reduction in the ionization time for grid overvoltages of two or three volts, however, when the load resistance is reduced. As yet, a theory to predict or explain the observed relation between ionization time and grid overvoltage has not been suggested.

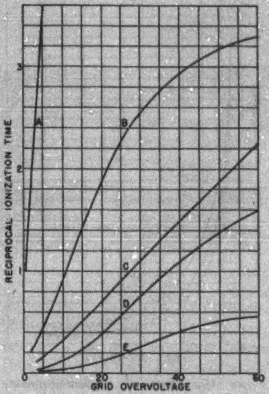

Figure 6. Reciprocal ionization times for figure 5

A—885 argon-filled thyratron, 300 volts on anode

B—*FG*-81 argon-filled thyratron, 180 volts on anode

C—*KY*-21 mercury-vapor thyratron, 1,000 volts on anode

D—*FG*-67 mercury-vapor thyratron, 1,000 volts on anode

E—*KU*-610 neon-filled thyratron, 750 volts on anode

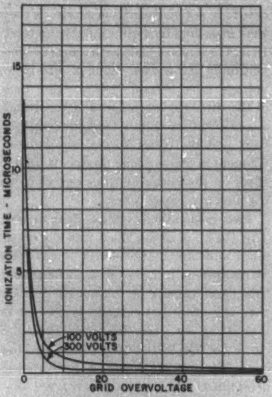

Figure 7. Effect of anode voltage on ionization time of a 2A4G argon-filled thyratron

Observations regarding individual tubes may be interesting. The electrode construction of an 885 differs radically from that of the other tubes and this thyratron has a very short ionization time, practically independent of anode voltage. In comparison with an 885, a *2A4G* has much longer ionization times at low grid overvoltages, but the ionization times are almost identical at the higher grid overvoltages. Compare figure 7 and curve *A* in figure 5. An *FG*-81, however, has an ionization time curve more nearly like that of the mercury-vapor tubes, although it is argon filled. Ionization times for neon-filled tubes were in all cases longer than the ionization times of argon or mercury-vapor tubes. Two *KU*-610 tubes were tested and gave slightly different results with 750 volts applied to the anode. These tubes would not operate consistently at anode voltages less than 500. These were old tubes, however, and this behavior may not be caused by the use of neon gas. Direct comparison of tubes filled with noble gases could not be made because the ionization times are affected by gas densities in the tubes and these were not known.

All tubes except the 885 show a variation of ionization time characteristic with different anode voltages. In all cases where anode voltage affected the ionization-time curve, an increase of anode voltage caused the knee of the curve to be more pronounced. Figures 7, 8, and 9 illustrate this effect for three types of tubes. The longer ionization time for large grid overvoltages with 100 volts on the anode is due primarily to an increase in the breakdown time (T_2 in figure 4), as the time lag T_1 is practically the same for all anode voltages when grid overvoltage is large. Note that there is little difference between the curves for an *FG*-57 and a *KY*-21 in figures 8 and 9. A second *FG*-57 showed ionization times consistently longer than those for the *KY*-21. It is common for mercury-vapor tubes of the same type and manufacture to differ from each other in characteristics, more than one differs from another tube of different construction and manufacture.

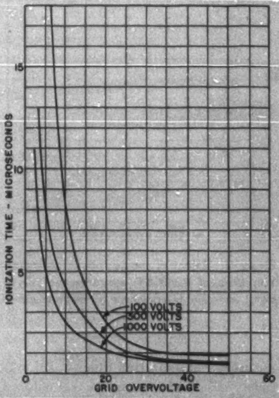

Figure 8. Effect of anode voltage on ionization time of an FG-57 mercury-vapor thyratron; mercury temperature 70 degrees centigrade

No change in the ionization time of several mercury-vapor tubes was found when the tube was biased to a large negative value (−50 volts bias for a tube with a critical bias of −5 volts) and the positive grid impulse increased so that the grid overvoltage was the same as before. Other circuits may give ionization times much longer than the values given here if they use high grid limiting resistors which introduce an additional *RC* lag.

An unusual phenomenon was observed while testing an 866 which had a special shield electrode placed around the cathode. The critical bias necessary with 400 volts on the anode changed within a few hours use from −4 volts to −60 volts. Loss of grid control continued as long as the filament was heated, although the anode voltage was zero and the grid bias −60 volts. A. W. Hull[2] mentioned this effect in 1929. The tube mentioned above was new, but the construction may be incorrect for use as a thyratron.

In some tubes, particularly the *FG*-17, a variation of ionization time for a given low grid overvoltage and low anode voltage was observed. The special 866 and the *KY*-21 also showed this effect, but the spread of ionization times was not as wide. An anode voltage of 300 reduced the variation, and 1,000 volts on the anode practically eliminated the effect. All of these tubes have filament-type cathodes and the effect is probably related to changes in effective cathode potential for different parts of the cycle. A difference in emissivity for different parts of the filament would exaggerate the effect, although the center of the filament supply might be at ground potential. The *FG*-17 tubes were several years old and probably not in the best condition, which may account for their pronounced variation of ionization time for a given low grid overvoltage.

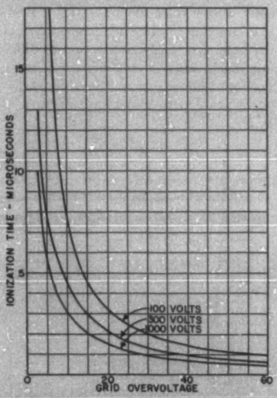

Figure 9. Effect of anode voltage on ionization time of a KY-21 mercury-vapor thyratron; mercury temperature 67 degrees centigrade

Variation of the ionization time characteristic of an *FG*-57 operated with an anode voltage of 300 is shown for three different mercury temperatures in figure 10. Mercury temperature has considerable effect at the higher grid overvoltages, but the curves coincide for low grid overvoltages. The temperatures indicated are not necessarily accurate, as they were measured by a questionable method. In fact, a series of tests with different temperatures and a fixed value of grid overvoltage gave erratic results. But each of the three curves in figure 10 represents a consistent set of data for some temperature, and the trend is certainly definite. Changes in temperature produce a similar effect on the ionization-time curves of all the mercury-vapor tubes.

Two cold-cathode tubes were tested. The *OA4G* is argon filled and its maximum ionization time is very long. The Strobotron is a neon-filled cold-cathode tube, and cannot be compared directly with the other hot-cathode types. It is interesting to note, however, that the curve for the Strobotron resembles the curve for the *KU*-610, a hot-cathode neon-filled tube, if the curves are displaced vertically until the minimum ionization times are equal (figure 5). Perhaps this is an indication that there is a fixed time lag necessary for initiation of emission, although the data are not sufficiently complete to prove this theory. Two values of capacitance were used across the anode and cathode of the Strobotron and the load resistor (R_2 in figure 1) was zero. Two microseconds were required to discharge a one-microfarad capacitor, and eight microseconds were required to discharge a ten-microfarad capacitor. These values are the time required for the capacitor to discharge. Discharge occurs after a delay, depending on grid overvoltage, as given in curve *F*, figure 5.

The results of these investigations show that the ionization time of mercury-vapor thyratrons may be as short as 0.3 microsecond if a positive impulse of sufficient magnitude is applied to the grid. Certain argon-filled types have even shorter ionization times. Characteristics of tubes of the same type may vary more than characteristics of tubes of slightly different construction. All tubes show the same general relation between ionization time and grid overvoltage. For most tubes the ionization time is inversely proportional to the grid overvoltage. There has been no theory suggested to explain this observed relation. However, these empirical data can be the basis for practical application and further investigation.

12-Kv Metal-Enclosed Bus and Switch Structure, Station C, Oakland, Pacific Gas and Electric Company

F. S. BENSON
MEMBER AIEE

H. E. STRANG
ASSOCIATE AIEE

THE East Bay metropolitan area, comprising the cities of Oakland, Berkeley, Alameda, Piedmont, and Richmond, is located on the east shore of San Francisco Bay. The population of these communities exceeds 500,000.

These cities are supplied with electric power from a high-voltage network consisting of 110-kv lines and substations located along the foothills in the easterly part of the cities; these high-voltage lines are fed from the hydroelectric transmission system; the substations connected to the high-voltage lines reduce the voltage to 12 kv, and these lower-voltage lines radiate to the several substations in these cities and, in turn, are connected to the steam-electric generating plant, station *C*, located on the Oakland water front.

The original steam-electric generating plant was built on the station *C* site during the late 90's; belt-driven, arc-light machines being the original installation. As the load in this area grew, the generating-station capacity was increased by means of engine-driven generators; these were replaced in due time with a 9,000- and a 12,000-kw vertical turbine generator. In 1922, a 12,000-kw horizontal turbine generator unit was added, and in 1929 further load growth necessitated the replacement of the 9,000-kw turbine, a 42,500-kva unit being installed in its place.

When the first turbines were installed about 1910, a new bus structure was located in the original building in which the early steam-driven units were installed, the steam units being located in a new structure adjoining the old. As the station was gradually increased in capacity, the bus structure was added to and some of the older oil circuit breakers were modernized to meet the increased rupturing duty.

By 1937 the load in this area reached a peak of approximately 140,000 kw. The steam-electric generating station had a maximum capacity of approximately 65,000 kva, and it was again necessary to increase the generating capacity of this station by the addition of a 50,000-kva steam-generating unit. The first steam turbines operated at 175 pounds steam pressure while the last unit put in in 1929 was a 425-pound unit. It was found that some simplification could be made in the boiler room and the efficiency of the plant increased by the addition of a 4,000-kva topping unit which would take steam at 425 pounds and discharge same at approximately 200 pounds into the older units. These additions would bring the steam-electric generating capacity up to approximately 120,000 kva.

As this plant not only supplies the surrounding communities but also acts as a steam standby to the general transmission system, it was necessary to make a connection of ample capacity between the high-voltage system and the steam station.

It was, therefore, decided to install a connection between station *X* (one of the high-voltage stations on the transmission system) and station *C* by means of a 110-kv underground oil-filled cable having a continuous capacity of 60,000 kva. The length of this cable run is approximately $3^1/_4$ miles. A 60,000-kva 110/12-kv transformer bank equipped with load-ratio control was to be installed at station *C* for the purpose of connecting the high- and low-voltage systems.

The addition in steam-turbine generating capacity and the connecting high-voltage cable greatly increased the interrupting duty on the 12-kv system at station *C*. The existing 12-kv switch equipment previously installed was found to be totally inadequate both electrically and mechanically for the new additions.

The arrangement of the old bus structure, the capacity of circuit breakers installed therein, the number of feeder positions available, together with the fact that there was no room for reactors on the feeders, made it impossible to use the existing structure. To have attempted to rebuild this structure in the existing space would have been most costly, to say nothing of the hazards involved in reconstruction.

After careful consideration it was found that the best and most economical plan would be to build a new switch house on property owned by the company, across a street from the main generating station. Circuit breakers and busses of the proper size could be installed without interfering with routine operating schedules; ample room could be provided for future growth; and most important, a serious congestion of existing duct lines and manholes adjacent to the present plant could be avoided.

Switchgear Design Objectives

After careful study the following specifications were established regarding the general type of switchgear and bus construction:

1. Operating conditions required a double bus with two oil circuit breakers for each feeder, transformer, and generator position.

2. The feeder oil circuit breakers should have an interrupting capacity of 1,000,000 kva; the generators, high-voltage transformer bank, and tie circuit breakers an interrupting capacity of 1,500,000 kva all at 12 kv. All oil breakers should contain as small a volume of oil as possible.

3. Each bus of the double bus should be in a separate fireproof room and each bus should be divided into two sections, these sections likewise to be isolated from each other by fireproof walls.

4. All oil circuit breakers should be isolated from the bus and the common feeder connection by gang-operated disconnecting switches, which should be mechanically interlocked with the oil circuit breaker so that they could not be opened when the oil circuit breaker is in the closed position.

5. The bus should be designed so as to be protected against short circuit by differential protection.

6. Current-limiting reactors should be installed on all feeders and generators.

7. The switchgear supporting and enclosing structure should be constructed of metal, using nonmagnetic metals where necessary to reduce cell heating due to eddy currents in the walls and barriers. Due attention should be given to design to prevent heating and damage to adjacent

Paper 39-127, recommended by the AIEE committee on protective devices, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted April 12, 1939; made available for preprinting May 31, 1939; released for final publication September 18, 1939.

F. S. BENSON is assistant engineer in the electric distribution department of the Pacific Gas and Electric Company, San Francisco, Calif.; H. E. STRANG is managing engineer of the large oil circuit breaker division of the General Electric Company, Philadelphia, Pa.

Credit is due S. J. Lisberger, chief of division of electric distribution, Pacific Gas and Electric Company, for his vision in the design of this new type of switching station and his courage in carrying it to successful completion. His assistance in the preparation of this paper is gratefully acknowledged.

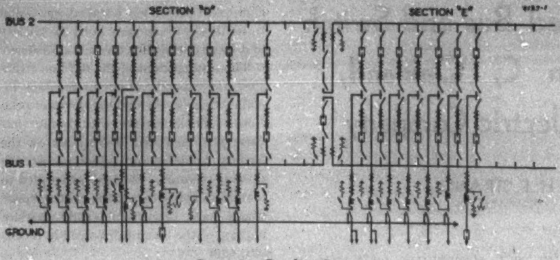

Figure 1. One-line diagram

parts of the structure in the event of short circuit. The entire structure should be well grounded.

8. The assembled switchgear at the factory should be given both a dielectric test and a heat run. The dielectric test should be in accordance with the standards of the AIEE. The heat run should consist of full-load current circulated through the main bus; the temperature of the bus bars and connections should not exceed a 35-degree centigrade rise above the air temperature in the cells. The temperature of the air in the cells shall not exceed a rise of 25 degrees centigrade above a room ambient temperature of 25 degrees centigrade.

In addition to the above main features there were many minor details such as position indicators, which should show open or closed position of the oil circuit breakers in order that the operator would not attempt to open a disconnecting switch without a visual marker indicating that the oil circuit breaker is open, even though a mechanical interlock prevents such operation; the insulated supports for the bus bar and all feeder taps should be designed to withstand a mechanical force produced by a short circuit of 70,000 amperes. The bus structure, switchgear, and all related 12-kv equipment should be designed for an insulating level equal to 23-kv-class equipment.

Suitable precautions should be taken to segregate the individual phases by suitable barriers and bushings to limit faults to single phase to ground, and to stop the migration of gas from one compartment to another.

A 23-kv test bus should be installed for the testing of feeder cables.

A ventilating system should be installed to provide clean, cool air to the switch house and also to remove quickly smoke and gases from the building in case of fire. Remote-controlled motor-operated dampers should be placed in the outlets of the forced-draft air ducts in each of the oil-circuit-breaker rooms to allow the operator to shut off the supply of fresh air if a fire occurs.

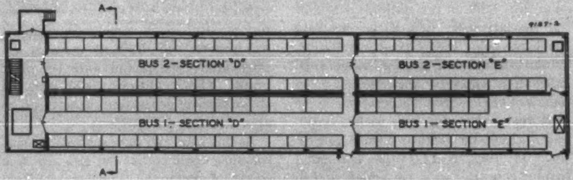

Figure 2. Main-floor plan—bus cells

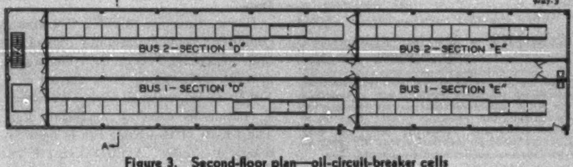

Figure 3. Second-floor plan—oil-circuit-breaker cells

After careful study it was decided that this new switch structure should be of radically different design than the older structures and the following features were decided upon:

No control conduits would be encased in the building structure, but would rather be run exposed; all of the heavy leads such as generator cables, outgoing feeder cables, etc., would be encased in duct structures which would be built in place after the building was finished. These features required a radical change in design, careful consideration of where the conduits were to run, and meant planning of conduit alleyways and runways. It also meant that the bus structure would have to be designed so that the control conduits from switches, instrument transformers, etc., would readily match the spaces provided for the conduit runs.

Accomplishment of Objectives

A. Switch-House Building

The new switch-house building was constructed with reinforced concrete walls, floors, and roof, which were supported by a structural steel frame. It is a two-story building and has a deep basement. Stairways are installed at the end of the building. Hatches are located in the first and second floors for hoisting switchgear compartments to the second floor or lowering generator reactors into the basements.

There are no windows or skylights in the building; their absence greatly reduces the amount of dirt and dust entering the station and also prevents leaks during inclement weather.

All illumination is artificial; ventilation of the building is obtained by means of an induced and forced draft fan and duct system. The air entering the building is cleaned by automatic self-cleaning air filters.

The first floor is divided into four large rooms, one for each bus and bus section. The metal-enclosed bus cells, feeder reactors, feeder-cable cells, and test-bus compartments are installed on this floor. See figure 2 for plan of cell arrangement.

The second floor is also divided into four large rooms, two of which are separated from the other two rooms by a long room. Control and similar conduits leading from the bus structure located on the floor below are brought into this room and racked in proper order and from there are run to the control house. Oil circuit breakers and their enclosing cells for each section are installed in each large room on this floor. See figure 3.

The ceiling of the second floor (above the oil circuit breakers) is built of sheet-steel shapes, which act as a protection for conduits in a conduit loft which is located between the ceiling of the second floor and the roof slab. See figure 4.

One side of the basement is walled off to provide a cable way. All the outgoing and incoming feeder cables enter the feeder cells from this subway.

The building was erected and completely finished by the contractors before any electrical installation was begun. No lighting nor control conduits were cast in the station walls or floor. All conduit work was run exposed and supported on the walls or ceilings. Thin-wall steel conduits with threadless fittings were installed for the control system.

Grooves, 12 inches wide and 2 inches deep, were cast in the first- and second-floor concrete slabs for receiving the steel channels forming the supports of the bus structure and oil-circuit-breaker cells. The channels furnished by the manufacturer of the cells were accurately leveled and then grouted in place, thus securely anchoring the channels in their proper position, also preventing any possible uplift of cells caused by the operation of the oil circuit breakers.

Figure 5. Switch house and yard

Holes were left in the first and second floors to allow for electrical connections between the oil circuit breakers and bus cells. Porcelain bushings were grouted in these holes providing the insulation required. Holes for bushings were also located in the partition wall on the first floor between the rooms for housing bus number 1 and bus number 2 and the reactor cell room. All holes were so accurately located that no trouble was encountered in lining up the cells on each floor and those on opposite sides of the wall.

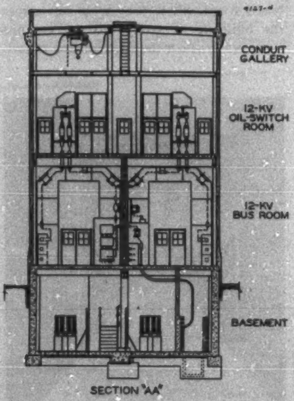

Figure 4. Typical cross section of switch house

Rectangular openings were also left in the floors and the partition walls for a variety of purposes, such as for the installation of lighting conduits, control conduits, communication ducts, and ventilating ducts, etc.

The company had undertaken no major construction of this character since 1929, at which time it was common practice to install 12-kv circuit breakers and bus equipment in concrete cell structures. In all these older designs, the control conduits had been encased in the building walls, floors, and the structure. In such installations the mass of control conduits was a real problem; they often interfered with the reinforcing steel in the building structure, were difficult to place, often requiring many bends which interfered with the pulling of the control wires; furthermore, they materially slowed up the construction of the building and often these conduits would be located in the wrong place.

Some difficulties had been experienced with heating of these conduits owing to their position with relation to the busses and feeder leads, and at times of short circuits, these conduits invariably picked up the ground current, often burning off and destroying the control system, then traversing the reinforcing steel, breaking out pieces of concrete from building walls far removed from the point of short circuit.

This new building design enabled the contractor to construct it at minimum cost and with minimum delay; there was no interference caused by other workmen attempting to install ducts and conduits in the floors and walls while building construction was in progress.

When the building was completed, the assembly of the bus structure and oil circuit breaker compartments began and was carried through to completion without delay, since there was no interference with other construction.

B. Switchgear Installed

The details of the metal-enclosed bus and oil circuit breaker, reactor, and test bus were designed by the manufacturer, and the structure was built to the specifications of the company's own engineering department.

The 12-kv bus and switch structure was built with two bus sections. Two generators, the 60,000-kva transformer bank, an auxiliary bus tie, and seven feeders were installed in section *D* and one generator, five feeders, were installed in section *E*. Spare feeder positions were provided in each section. The bus extension, when necessary, will be made on the end of section *E*.

The feeder oil circuit breakers are bottom connected, low-oil-content type, mounted in steel cells. Complete phase segregation is accomplished by grounded metal barriers between phase compartments. These oil circuit breakers are mounted on the floor above the bus structure. For ease in handling, the bus compartments were manufactured in units corresponding to each feeder, generator, or transformer. These were assembled at the factory in proper relation to each other and the disconnecting-switch compartments, and all copper permanently

Figure 6. Oil-circuit-breaker room

mounted in place. See figures 10 and 11. The main bus has a continuous rating of 3,700 amperes at 60 cycles. Each bus is made up of double copper channel sections mounted face to face. A special type of support clamp was developed to anchor this assembly to one of the porcelain insulators in alternate cubicles with flexible connections between each second unit. Joints between the balance of the cells were made with silver line-contact splice plates. Nonmagnetic steel was used where necessary in order to prevent undue heating, and the whole assembly given a full-current heat run. The bus insulators and structure were designed to withstand mechanical forces to be encountered up to the rating of the oil circuit breakers.

Figure 7. Conduit loft above oil-circuit-breaker room

The disconnecting switches mounted in steel compartments above each of the busses are gang operated, the six switches on both sides of a breaker being operated from one gear-type mechanism. They are mechanically interlocked to assure:

(*a*). Circuit breaker in open position before operating switches. This is accomplished by a positive interference block which prevents rotation of crank shaft, either opening or closing, except when breaker is in open position.

(*b*). Full operation of disconnecting switch before breaker can be operated either electrically or manually. Since the breakers and switches are on different floors, it is considered important to guard against partial operation of the switches. This is done by breaking the trip-free latch on the breaker mechanism for all disconnect positions other than fully open or fully closed.

The feeder reactors consist of three single-phase units installed in nonmagnetic housings.

To provide ventilation, the cells are built with louvers, backed with a fine wire mesh.

C. LIGHTING

The lighting for the oil-circuit-breaker cells on the second floor presents no difficulty. Prismatic lighting fixtures having an intensive characteristic were installed.

The lighting for the bus structure on the first floor proved much more difficult. The gang-operated disconnecting switches were installed at the top of the structure just below the steel crossover in such a position that an attendant on the floor can readily see the disconnecting-switch blades. The operation indicators showing the open and closed position of the coil circuit breaker are installed on the lower side of the crossover cells. To give proper illumination to these devices and prevent the light from blinding the operator required several trial installations.

A fixture used for kitchen illumination was obtained. The light was directed up against the top of the structure. The bottom of the fixture is made of a translucent material allowing some light to reach the floor; this source is not bright enough to blind the attendant while looking upward to see the operation indicators. These fixtures were suspended approximately eight feet below the bottom of the crossover cells. With the fixtures at that elevation, the illumination on the blades of the disconnecting switches was such that they could be plainly seen through the glass window.

One feature to be guarded against in future installations developed after the installation. The steel cells are wide and high, and when painted black both inside and outside, it is difficult to get enough light in the cells, even when using two 150-watt lamps supplied with portable cords, the black of the cell finish absorbing the light. To overcome this difficulty, it is planned, in future installations, to paint the cells a light color such as cream.

D. CONDUITS

The steel compartments were constructed with conduit boxes located at accessible places on the top of the cells.

Thin-wall conduits were installed through the openings in the walls, ceilings, and floors from the bus and switch cells to the conduit loft and conduit room. Here they were racked in orderly tiers and run exposed to a point in the switch-house building opposite the switchboard room, where they were run across the building in groups to the conduit room underneath the switchboard room.

Figure 8. Conduit room between oil-circuit breaker rooms, second floor

Figure 9. Bus room, first floor

Figure 10. Factory assembly of bus housings, showing spare positions

Figure 11. Factory assembly of bus housings

Such a conduit installation, using threadless fittings, enabled the construction department to keep all conduits out of the floors and walls of the building. The areas left around the conduits when installed in wall and floor openings were grouted in with cement, thereby preventing the migration of gas from one room to another.

E. GROUNDING

The metal structure made grounding relatively simple. Copper conductors having a cross-sectional area of 500,000 circular mils are connected to each end of the steel supporting channels for the bus structure. These cables were then connected to the general copper grid comprising the station grounding system. All equipment in the station is grounded by conductors installed as a loop connection. This reduces the resistance to ground and also provides a parallel path for the ground current to flow in event of trouble.

Conclusions

This type of structure and its installation at station *C* showed advantages which are summarized as follows:

1. With a complete factory design and fabrication the customer is relieved of the burden of preparing many detail drawings such as detailing of the bus bars, their enclosing cells, selecting of proper shape of current transformers to fit the structure, and the preparation of a mass of detailed instructions for type of connectors to be used, etc. It is also of material advantage to the field crews to have everything delivered complete and plainly marked as it saves much time in obtaining various fittings and devices from a large group of manufacturers. With the specifications requiring the furnishing of the entire structure complete in all details, the field erection time is greatly reduced.

2. The building can be completely erected with a minimum of delay, and therefore reduction in cost, because no conduits, miscellaneous equipment, etc., had to be installed in the building structure. This simplified the problem of the building contractor, completely eliminated errors in location of conduits, and reduced the number of spare conduits that must be installed since all of the conduits are run exposed.

3. The equipment is entirely self-supporting; the cells are all built in units. If any repairs have to be made, it does not affect the adjacent structures.

4. The cells and all related equipment being furnished by one manufacturer can be set up in the factory, given heat-run and voltage tests; any errors can be detected before the equipment leaves the factory. All parts of the structure can be completely marked so that ready assembly can be made in the field. By proper scheduling of shipments the apparatus can be set in place about as fast as it arrives, thus saving considerable time in the storing of equipment.

5. The metal-enclosed bus and circuit-breaker structure is entirely fireproof; the only inflammable materials are the insulation around the current transformers, the compound in the potential transformers, the limited quantity of oil in the type *H* oil circuit breakers, and short lengths of single-conductor varnished-cambric-insulated flameproof braided cable.

6. This type of metal cell structure is practically rodent proof, as there are no cracks or gaps of any size between the doors, cells, etc. With proper precaution taken for isolation between phases, ionized gases generated at the time of short circuits can be practically confined in a small area. The structure is much lighter than the similar type of concrete structure that would be required. It also occupies less space in the building. It does not have to be tied to the building structure as was the case with concrete cells. Where provision must be made for structures to stand earthquake stresses such as in the San Francisco Bay area, the reduction in the total weight is a decided advantage.

7. The cells present a very neat appearance. All live parts are totally enclosed. The structure is solidly grounded. It is believed that this is the safest type of switchgear that can be used, and it offers the minimum hazards to the operating and maintenance personnel.

8. Purchase of the complete structure from one manufacturer not only facilitates construction but reduces by astounding quantities the number of requisitions, bills, and similar bookkeeping details in handling the hundreds of parts that must be obtained and stored for the installation of this type of equipment if it were constructed in the manner previously used, namely, building concrete, buying each individual group of parts from separate manufacturers.

This equipment has been in service only about six months [up to June 1939]. No troubles have developed since it was put into operation; other than the painting of the cells we would make no changes in design if the job had to be done over. Field erection and handling met all expectations and the over-all cost of the installation is less than similar types previously used.

Discussion

For discussion see page 1080.

Electrical Equipment of the Union Pacific Steam-Electric Locomotive

M. R. HANNA
ASSOCIATE AIEE

J. F. TRITLE
ASSOCIATE AIEE

THE development of the steam-electric locomotive for the Union Pacific Railroad represents the culmination of more than two years of co-operative design and research by scientists, engineers, and officials of the railroad and of the various manufacturers of equipment for this outstanding example of modern motive power. It is the intention of the authors to deal primarily with the electrical details but a comprehensive picture of the general features of this recent development is included.

A number of departures were made from conventional designs in order fully to utilize the possibilities of this new type of motive power. New methods of construction were devised permitting material reductions in weight and space requirements.

New generator ventilating-fan designs were required for satisfactory noise levels at tip speeds much higher than usual. Armature-excited exciters were utilized to assist in maintaining uniform response of power and electrical braking under a variety of operating conditions, particularly in multiple unit.

The development of an electrical control system capable of insuring and controlling maximum output over the full range of steaming conditions also presented a number of interesting and difficult problems.

The braking resistor is particularly noteworthy from the standpoint of methods of construction, the energy dissipation rates per unit surface, and the method of forcing cooling water through the tubes.

Although multiple-unit operation of electric locomotives is commonplace and there are well-established design practices used in such applications, yet new problems were presented in designing multiple-unit control of steam-electric units. A complete system of electric control was devised which permits, for the first time, full multiple-unit operation of two steam locomotives from the operating cab of either locomotive.

The essential parts of each of the Union Pacific locomotive units are:

1. A high-pressure oil-burning steam boiler
2. An auxiliary set, turbine-driven, for operating pumps, blowers, and auxiliaries
3. A complete automatic control for supplying adequate steam as demanded
4. A main geared turbine generating set for traction power (direct current)
5. An a-c generator on same shaft for train air conditioning, traction-motor blowers, and other accessories
6. Air-cooled condensers for returning used steam to boiler as water
7. Six axle-hung traction motors geared to main drivers
8. A main control system for automatic and manual control of motor combinations during acceleration
9. An electric braking control system automatically or manually blended with the air brakes when the motors act as generators during braking
10. Electric couplers and accessories which permit operating the locomotive units singly or in multiple unit during acceleration and braking
11. Three separate train-control signal systems to conform to the different lines over which the locomotive will operate

The 5,000-horsepower locomotive is made up in two cabs, each powered with an oil-burning water-tube boiler of the forced circulation type, supplying superheated steam at 1,500 pounds and 920 degrees Fahrenheit. On level track a 1,000-ton train can be hauled at 90 miles per hour, and at lower speeds on the 2.2 per cent grades without a helper. In emergency, it may safely operate at speeds as high as 125 miles per hour. The steam from the boiler drives a turbine unit consisting of high- and low-pressure rotors driving a single helical gear. Direct connected to the driven shaft is the two-armature d-c generator, a 60-cycle auxiliary generator, and an exciter of the metadyne type.

A main handle and a selector handle on the master controller in the operating cab permits the engineer to control the supply of power to the six traction motors on the driving axles and to connect these motors in three combinations, series, series-parallel, and parallel. A braking handle on this same controller in conjunction with certain auxiliary devices, permits the engineer to convert the motors to generators for electric braking and to blend the electric braking with the air brakes automatically and manually for a wide variety of operating conditions. A novel design of braking resistor converts the electric braking energy into heat. This heat is transferred to cooling water, circulated through the stainless steel tubes of the resistor, and dissipated in the main air-cooled condenser. Especially noteworthy is the provision for multiple-unit operation of the boiler, the main power plants, and the motors on both units from the operating position on either unit. With the variation of demand from the turbine generating set, the steam equipment automatically responds with greater or less steaming by means of a complete automatic control.

Steam-Plant Control

When making a cold start a propane-fired auxiliary boiler is used for low pressure steam for heating and atomizing the "bunker *C*" fuel oil. The turbine-driven auxiliary set is next started and is driven by its battery-operated starting motor in order to provide feed water, combustion air, and fuel oil to the Babcock and Wilcox main boiler. With the auxiliary set in operation and atomizing steam available, each of the two burners in the main boiler is lighted by manually closing the ignition switch which lights a propane torch by sparking ignitors.

After a short delay fuel oil is admitted automatically to the burners and upon establishment of the oil flame, indicating flame failure photocells act to cut off the propane torch and ignitors. If the flame is not established within a definite time or subsequently fails, the lighting cycle is automatically repeated. This igniting cycle will be repeated five times if the oil does not ignite after which it locks out and must be reset by hand.

When the main boiler pressure rises to approximately 500 pounds, steam is admitted manually to the turbine of the auxiliary set. When the boiler pressure reaches 800 pounds the starting motor is automatically disconnected from the battery and operates as a d-c generator supplying all d-c driven pumps. Subsequently, when the battery-charging motor generator set is started the d-c pump motors are automatically transferred to this set and the starting motor of the

Paper 39-139, recommended by the AIEE committee on transportation, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted April 22, 1939; made available for preprinting May 10, 1939; released for final publication August 28, 1939.

M. R. HANNA is engineer of the motor division and J. F. TRITLE is engineer of the control division of the transportation engineering department of the General Electric Company, Erie, Pa.

auxiliary turbine set is electrically isolated.

The fuel and air supply to the burners and water supply to the boiler are regulated by the Bailey Meter steam-plant control when starting and when operating normally. The fuel and water pumps and the draft fan are built integral with the auxiliary set. The speed of this set is varied in response to changes in steam flow and water level providing an easy method of changing fuel, air, and water flow simultaneously in approximately the correct proportions.

The fuel pump and draft fan are designed to supply fuel and air slightly in excess of that required for a given water flow. Accurate adjustment of the air flow is made by an automatic damper under the control of a boiler pressure controller, and accurate adjustment of the fuel-oil flow is maintained by a by-pass fuel valve under the control of an oil-air flow ratio controller. The complete steam plant control, therefore, regulates fuel, air, and water to the boiler automatically in response to power demand, maintains water level, and insures correct combustion. The condenser inlet louvres are controlled by a thermal device actuated by condensate temperature.

In emergency, the automatic features may be cut out and the various functions controlled manually.

Main Traction Generator

The main traction generator unit consists of a pair of complete generators built in a single frame with armatures back to back. Because of the demand for a large amount of 60-cycle power to be used on certain of the trains hauled by this locomotive and because of the relatively large savings in cost and weight of the main gear reduction unit by using the highest possible speed on the driven shaft, 1,200 rpm was chosen as the operating speed of the generator set. While this was an abnormally high speed for which to design a d-c machine of the capacity desired, the advantages seemed sufficient to compensate for the mechanical design difficulties involved.

The high speed of the generator together with the severe weight and space restrictions made it necessary to depart somewhat from the usual mechanical construction. To provide rigidity with minimum weight, the tandem armatures are built on a single hollow steel cylinder with stub shaft extensions at each end. In order to avoid excessive commutator surface speed, it was necessary to reduce their diameter to a point which precluded passing the armature ventilating air under the commutators. Ventilation is through the risers which are of the involute type to serve also as equalizers.

The armature ventilating fans which are mounted in the central space between the two armatures, figure 2, are of the laid back aphonic type. By use of this specially developed blade shape and other acoustic considerations it was possible to design the compact self-ventilated generator for a noise level considerably below that which would have been obtained with conventional fan design at this tip speed. The exhaust ventilating air is collected in a scroll and is normally discharged through the cab roof, although the discharge may be regulated by a damper for cab temperature control.

The generator frame, split longitudinally for ease of assembly, is of skeleton construction and is illustrated in figure 3. The armature bearings are sleeve type, and the lubricating oil is circulated by pumps through coolers and filters before returning to the bearings.

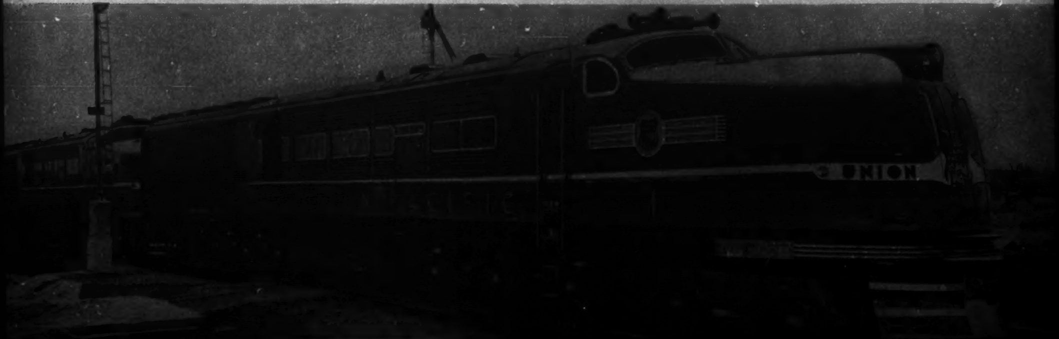
These two component generators built into one frame are normally connected in series with their mid-point grounded, thus limiting the insulation stress in all the transmission equipment to not over half of the total voltage generated. The traction generator unit is separately excited by a metadyne exciter which, through a speed sensitive control device and depending on the turbine power available, imparts to it output characteristics as shown in figure 4. The electrical proportions of the machine are such that it will rate full horsepower continuously at any point shown on these characteristic curves, from 3,200 amperes up to 1,340 volts. The nominal rating of the generator unit is 2,500-horsepower input at 1,200 rpm. The wide range of current and voltage over which the machine will rate continuously is typical of generators used on internal-power locomotives. By multiplying maximum continuous rated voltage by maximum continuous rated current, one obtains a much better measure of the service capacity of the generator than by merely stating the rated horsepower input.

Auxiliary A-C Generator and Metadyne Exciter

The auxiliary a-c generator and metadyne exciter are built into a compact two-unit machine having a centrally located ventilating fan and a single self-aligning antifriction bearing, the driven end of the set being supported on a steel-disk type of flexible coupling through which the auxiliary unit is attached to a shaft extension of the main traction unit.

The a-c machine is of the salient-pole rotor design with distributed stator windings. The continuous rating is 480 kva, 230 volts, three phase, 60 cycles. It is of conventional design except for the use of heatproof insulation and aluminum frame to reduce size and weight. The primary purpose of the alternator is to supply lighting, heating, cooking, and air-conditioning power to streamlined passenger trains. It is used on the locomotive to supply two traction-motor blowers, the speed-control governor, the main air compressor, the 130-volt and

Figure 1. 5,000-horsepower double-unit streamlined steam-electric locomotive for Union Pacific Railroad



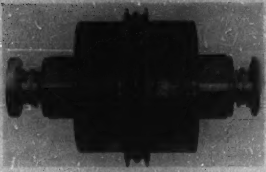


Figure 2. Armature of traction generator

64-volt motor generator sets, and through small transformers, the 12-volt headlights and part of the 115-volt lights. A dynamic type regulator is provided to hold the three-phase lines at a constant voltage over a wide range of load. Excitation of the alternator field is from the 130-volt d-c system.

In common with all metadyne-type machines, this exciter is characterized by the fact that it is armature excited. One of its most valuable properties lies in its inherent characteristic of delivering a definite current output regardless of load circuit resistance, the value of the current being approximately proportional to the current in one of its low-wattage control fields.

This exciter has two distinct functions. During the normal operation of the locomotive as a propulsion unit, it is used to excite the field of the main traction generator. However, when it is desired to use the locomotive to assist in decelerating the train or in holding it on long mountain grades, the exciter output connections are transferred from the generator fields to the traction-motor fields. It is here (as well as for multiple-unit propulsion operation) that the inherent constant-current characteristics of the metadyne are of special value, for while the resistance of the traction-motor fields may conceivably change by 50 per cent or more due to variations in temperature, the braking characteristics remain essentially unaltered.

Traction Motors

A locomotive with a weight of 354,000 pounds on its six driving axles and an operating range extending from a maximum speed of 125 miles per hour at one extreme to a maximum tractive effort of nearly 90,000 pounds at the other, presents a broad problem in traction-motor design. As usual in traction motors, much of the design was dictated by the necessity of mounting the motor between the wheels on standard track gauge. Minimum weight was of paramount importance. The motors, figure 5, are axle mounted, thus permitting the use of small wheels (44 inches). This gives the lowest possible cab floor height and the maximum room for apparatus in the cab.

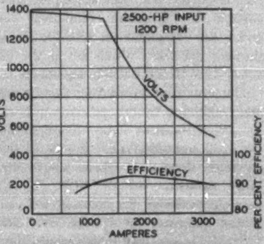

Figure 4. Characteristics of 2,500-horsepower traction generator with speed control

The characteristics of the traction motor on constant voltage are shown in figure 6. The motor has eight poles with multiple-wound fully equalized armature. Motor brushholders are supported on a movable brush yoke which can be rotated for inspection by means of a pinion engaged in a gear mounted on the yoke. Each brushholder can be brought in turn opposite the bottom inspection opening.

In service the motors operate on a constant-horsepower variable-voltage generator characteristic, and the six motors per cab will transmit 2,500-horsepower turbine output at any speed up to 125 miles per hour. Each motor is normally blown with 2,000 cubic feet of air per minute. The normal continuous rating is 32,000 pounds tractive effort per locomotive cab. Maximum grades of the order of two per cent, of considerable length, are encountered in transcontinental service. Such grades impose a heating problem in the electrical traction equipment, which is relatively difficult as compared with that encountered in operation on level track. To permit the the handling of heavy trains in transcontinental service without the use of helper locomotives on the heavy grades, high-speed operation of the traction blowers is provided, giving 4,000 cubic feet of ventilating air per minute per motor. The rating obtained with this ventilation is 40,500 pounds tractive effort per locomotive cab.

The traction-motor armature bearings are of the grease-lubricated cylindrical-

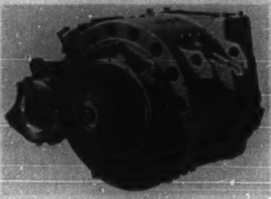

Figure 5. Traction motor

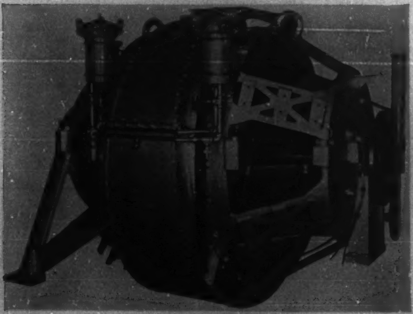

Figure 3. 2,500-horsepower traction generator

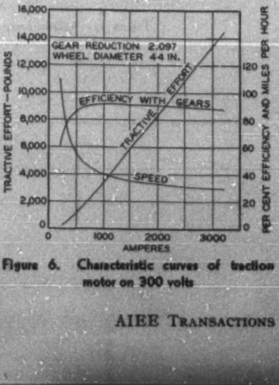

Figure 6. Characteristic curves of traction motor on 300 volts

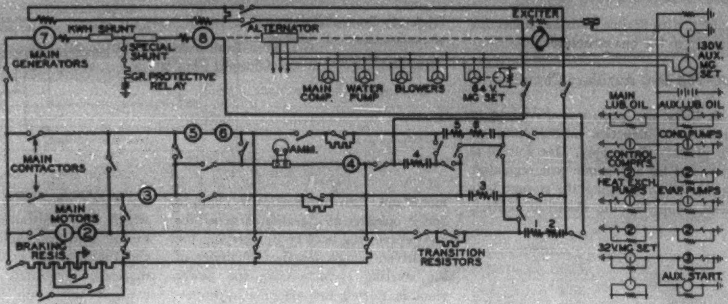
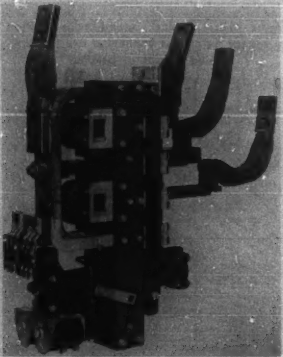
Figure 7. Schematic diagram of main and auxiliary power circuits



roller type. The suspension or axle bearings are split sleeves lubricated by wool waste wicks. The wicks are held in contact with the axles by a spring mechanism, and oil is supplied from a constant-level reservoir.

The high speed and heavy loading presents a difficult gear problem. In order to eliminate mounting distortion, the gear rims are bolted with body bound bolts to the gear centers which are finish machined after mounting on the axles. The stiff tacky gear lubricant generally used on axle-mounted traction motors was considered unsuitable for the high-speed operation, so provision was made to use oil with "extreme pressure" properties. In addition to providing a reservoir for the lubricant the gear case is constructed in such a way as to lubricate the gear mesh by splash at low speed and by jet action at high speed.

Figure 8. Electropneumatic reverser with flexible leads for connecting direct to bus structure



Compressors

On each unit of the locomotive there is a two-stage aluminum-frame air compressor having a piston displacement of 186 cubic feet per minute which furnishes air for braking and for control apparatus. The compressor is driven by a three-phase 60-cycle 220-volt induction motor, through herringbone gearing. The control is of the start and stop type. An unloader is installed in the discharge pipe between compressor and reservoir to reduce the starting-torque demand on the motor.

In addition to the main a-c motor-driven compressor, each locomotive unit has two d-c motor-driven compressors with a combined piston displacement of 36 cubic feet per minute. Their chief function is to charge the control system for the initial start of the locomotive before steam is generated. During regular operation, if the air demand is such as to cause the gauge pressure to fall below approximately 115 pounds per square inch, they also automatically assist in supplying air to the main reservoir.

Main Power Circuits

Figure 7 is a schematic diagram of the main power circuits. The double armature generator and a direct-connected metadyne exciter are driven by the main turbine through suitable gearing. The exciter supplies excitation for the generators when motoring, and for the traction motors during electric braking. A maximum generator voltage of 1,400 is used during motoring. The midpoint between the generators is grounded, so that no point in the main circuit is normally more than 700 volts from ground potential. The main circuits include a traction-motor ammeter shunt, a kilowatt-hour meter shunt, and a special shunt to energize the current-limit and backward-transfer relays as well as a differential field on the exciter to impart a differential characteristic to the shunt generators. Electropneumatically operated contactors, are used to connect the motors in three speed combinations of six, three, or two motors in series, with provision for two speed combinations of four and two in series with any pair of motors cut out. Transition resistors are used to prevent interruption of power to the motors during transfer of the motors from one combination to another. The motors are reversed by a unique design of reverser,

Figure 9. Master controller with cover removed

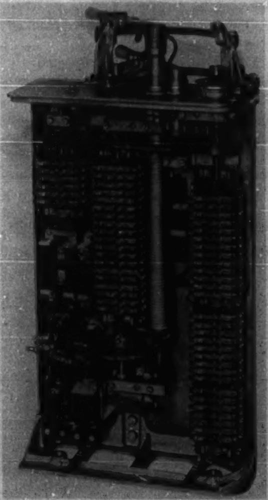


figure 8, with flexible leads for connecting directly to the bus structure.

130-Volt D-C Auxiliary Circuits

A 40-kw d-c generator driven by a three-phase induction motor furnishes the primary d-c supply. Its voltage is controlled by a dynamic-type regulator. It is used for charging the storage batteries, supplying the electrical control, boiler control, miscellaneous pumps, and other auxiliary circuits. It may also be used to supply power for the starting motor of the auxiliary turbine set when the induction motor is energized from an external source.

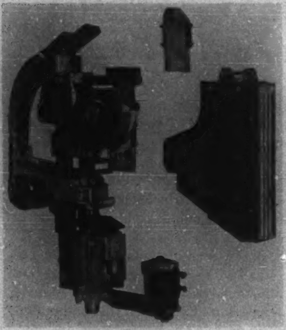

Figure 10. Electropneumatic contactor with arc chute removed

The starting motor drives the auxiliary turbine set, when starting the main power plant, in order to supply fuel oil, combustion air, and feed water to the boiler until sufficient steam is generated in the boiler to operate the auxiliary turbine. The electrical connections to the starting motor are then automatically changed and it operates as a regulated generator and relieves the battery by carrying the d-c driven pumps for the remainder of the starting cycle. After the power plant is started the machine is disconnected from the circuit.

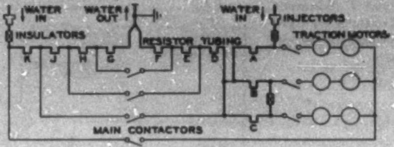

Figure 12. Schematic diagram of connections of braking resistor

64-Volt D-C Auxiliary Circuits

Direct current at this voltage is required for contemplated hauling of existing streamlined trains. It is supplied by a 7.5-kw generator driven by a three-phase induction motor. No voltage regulator is provided for this generator, but a three-position switch gives a choice of three battery-charging rates. Separate regulated excitation of the generator is taken from the 130-volt system. When pulling streamlined trains the set supplies electric control for the straight air brake system, control for the air-conditioning equipment, telephones, mail-room buzzer, emergency lights in the train, and charges the 64-volt battery in the baggage car. When pulling standard Pullman cars or freight, the set is used only for operation of the telephones on the locomotive.

Master Controller

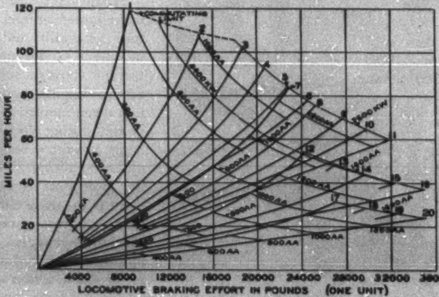
Figure 9 shows a front view of the master controller with the cover removed. This controller has three handles, mechanically interlocked to prevent improper operation, by which the main power circuits are controlled. The motoring handle operates a cam shaft and control fingers which vary resistance in series with the exciter field and establish the circuit for the magnet valves of the electropneumatically operated contactors which connect the main traction motors in various combinations required for accelerating and braking. There are 21 notches on the dial ring of this handle.

The brake handle drives its control cylinder through the long spring mounted concentric with the operating shaft. When the handle is moved into any one of the 20 notches on the dial ring the spring will exert a torque to turn the control cylinder through the gear and sector at the bottom of the controller to the position selected on the dial ring. The movement of the cylinder, however, is governed by the notching mechanism engaging the notched wheel on the end of the shaft. The notching mechanism is controlled by current and kilowatt relays connected in the motor circuits during the braking cycle.

The selector handle has seven positions; off, forward series, series-parallel, and parallel, and reverse series, series-parallel, and parallel. In the series positions the motors are connected six in series. In the series-parallel positions the motors are connected three in series and two groups in parallel while in the parallel positions the motors are connected two in series and three groups in parallel.

Figure 11. Water-cooled braking resistor

Figure 13. Typical speed-braking effort curves for six motors connected two in series, three groups in parallel



The dial rings have fluorescent-paint numerals and are illuminated at will by argon glow lamps mounted on the motoring and brake handles.

Main Contactors

Figure 10 shows one of the main electropneumatically operated contactors with arc chute removed. These contactors are mounted in dustproof compartments underneath the locomotive and are equipped with powerful magnetic blowouts for rupturing the main circuits. The flexible braided connections at the back of the contactors facilitate direct connection to the bus structure. The contactors are closed by air pressure against a powerful spring located in the operating cylinder. This spring insures a very rapid and positive opening of the contact tips when the air pressure is removed.

Braking Resistor

The braking resistor, a plan view of which is shown in figure 11, consists of approximately 350 feet of seamless drawn stainless-steel tubes which make up the resistor sections and through which cooling water is circulated. These tubes are connected at the ends by cast return bends of the same material and the complete unit is assembled on insulated supports in the form of an oblong spiral. Each tube is rigidly supported at the center and the ends are supported in such a way as to allow for contraction and expansion during electric braking. The tubing is arranged in two parallel hydraulic circuits with separate inlets and a common outlet which is rigidly grounded. The inlet pipes are insulated from ground by a special high-temperature moulded tubing.

Ahead of each insulator tube is mounted an injector, supplied by steam from the main boiler, and designed to force the cooling water through each hydraulic circuit at a rate of 12,500 pounds per hour under normal braking conditions with the water at an initial temperature of 230 degrees Fahrenheit. The resistor has capacity to dissipate 3,600 kw continuously but this maximum rating is used only when decelerating the train from maximum speeds. When braking at maximum capacity approximately 50 per cent of the cooling water is converted into steam and the mixture passes through a steam separator. The water is returned direct to the hot well while the steam is passed into the main condenser.

An electropneumatically operated valve controls the admission of water to the inlet end of the resistor and a similar valve of larger size is placed between the separator and the hot well to prevent bypassing the condenser when the resistor is not in use. An air-operated diaphragm type of valve controlled by a magnet valve governs the flow of steam into the injector. Protective relays prevent the establishment of the braking circuit through the resistor unless the tubes are full of water.

Figure 12 shows the connections of the tubes electrically and hydraulically. Sections *A*, *B*, and *C* are in series hydraulically, but in parallel electrically so as to serve as balancing resistors for each pair of motor armatures. Sections *D* to *K* are in series electrically, and carry the total current of all six motors connected two in series and three groups in parallel. Four values of resistance are available, the circuits being so arranged that each hydraulic half of the resistor is approximately equally loaded at all times. Each of these resistance values gives a group of braking notches as shown in figure 13, the notches in each group being obtained by controlling the motor field strength.

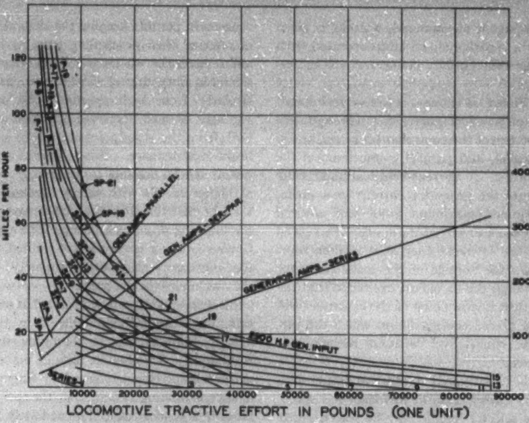


Figure 14. Typical speed-tractive effort curves for series-series-parallel and parallel connections of motors

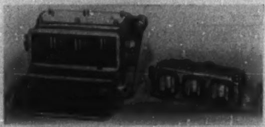
Figure 15. Plug and socket of three-phase 450-ampere coupler



Motoring With Automatic Transition

When accelerating the train from rest the selector handle of the master controller is placed in the parallel position and the motoring handle is moved slowly through the first few notches to take slack and get the train in motion. The motoring handle may then be advanced as rapidly as desired up to the 21st position. The movement of the motoring handle cuts out sections of fixed resistance in series with the field of the metadyne exciter. However, the exciter field current is limited by the automatic load-regulating equipment which takes over control as soon as the motoring handle cuts out sufficient resistance to permit regulation at full output.

Transition of the motors from series to series-parallel and from series-parallel to parallel takes place automatically under the control of a voltage relay when the generator voltage reaches the proper predetermined value. The locomotive speeds at which transitions occur depend upon the position of the motoring handle, the transition points being higher for the higher notches.

If the maximum permissible generator current is approached as in ascending an increasing grade, a backward-transfer signal light flashes at the operator's position warning him to move the selector handle back to the next lower position. The backward transitions take place in response to the backward movement of the selector handle. If wheel slippage is encountered, warning is given by a separate signal lamp operated from four differentially connected voltage relays.

Figure 14 shows a set of typical speed-tractive effort curves for representative notches of the controller for series, series-parallel, and parallel connections of the motors. A current relay automatically limits the generator current to a predetermined maximum value and a speed governor driven at the synchronous speed of the 60-cycle alternator further regulates the voltage of the main generator through the metadyne exciter so that the output in any notch of the controller will not exceed the maximum which the turbine can deliver without reducing its speed.

If it is desired to start and operate a very heavy train at less than full speed, the selector handle may be placed either in the series or the series-parallel position, which prevents the motors transferring to the next higher speed combination. The main handle may be notched backward or forward at will to maintain a train speed best suited to the profile.

Motoring With Manual Control

If for any reason the engineer wishes to eliminate the automatic features, a switch may be thrown which by-passes the automatic devices and cuts out the automatic transitions. The locomotive then operates only in the connection called for by the selector handle, and the engineer must watch the generator speed indicator and motor ammeter to avoid overloading either the turbine or the generator.

With a light train, or on a downgrade, the engineer may start either in series, series-parallel, or parallel by placing the selector handle in the desired position before notching out the motoring handle. With heavy trains the start is made with the motors in the series connection and transitions are made manually by backing off the motoring handle a few notches before moving the selector handle to the next higher speed position. The backward transfer light, as in automatic operation, functions and acts as an additional warning if the maximum permissible generator current is approached.

Manual Electric Braking

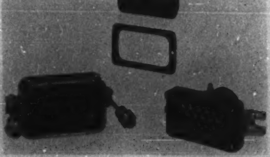
Manual control of the electric brake is provided to permit its use for slowing down the train and for controlling the speed and holding the train on grades without the use of air brakes. This arrangement permits keeping the air brakes in reserve when descending long grades and relieves the wheels and shoes of considerable duty during slow downs, particularly from high speeds. The advantages of such operation are apparent both from the standpoints of safety and brake maintenance. Where curves permit, it is also possible to descend grades at higher speeds with safety because of the fact that the air brakes are in reserve for stopping in an emergency. The continuous braking energy is not limited to the continuous dissipating capacity of the mechanical brake parts.

Electric braking can be initiated at any time the accelerating handle is in the "off" position by moving the brake control handle. This handle may be moved one notch at a time to control the amount of electric braking as desired by the operator or it may be advanced immediately to any notch. When advanced immediately, the notching takes place automatically and is controlled by a suitable current-limit and kilowatt-limit relay. If it is desired to descend a grade at approximately uniform speed the handle can be placed immediately in the correct notch for the desired speed. To maintain maximum electric braking as the train slows down, the handle is advanced immediately to the last notch. Under this condition the notching will be automatic and the braking will be under the control of the kilowatt and current-limit relay.

The settings of these relays during manual control of braking corresponds to the continuous braking ability of the motors because sufficiently long grades may be encountered to require operating the motors at this rating when using electric braking alone. The relay settings are lower than those used for maximum automatic electric braking where the train is slowed down by using air in combination with electric braking.

The progression of the braking-controller cam shaft either automatically or manually energizes the braking control circuits in proper sequence to change the braking-resistor connections and to control the field strength of the traction motors. This is accomplished by controlling the field of the metadyne exciter used for motor field excitation, in proper sequence to provide the desired graduations in braking effort.

Figure 16. Plug and socket of 24-point train-line coupler



Automatic Electric Braking

The locomotive is equipped with "automatic air-brake control equipment" for conventional steam trains and "high-speed straight air control equipment" for use on streamlined trains. Automatic control of the electric brake may be used in combination with both systems. When used, the full capacity of electric brake is available, assisting the air brakes in slowing down and stopping the train. The arrangement is such that air pressure to the driver brake cylinders is suppressed when the electric brake is functioning normally.

The control of the electric braking has been co-ordinated with the control of both air-brake systems to provide a braking effort on the drivers slightly less than that which would be obtained with the air brakes over the speed range involved. This adjustment is used in order to permit slightly heavier braking on the train than on the locomotive so that the locomotive will stretch the slack during a stop.

In order to make use of the electric brake in combination with the air, the operator places the manual braking controller handle in the first notch before he starts an air application. He is then free to make the complete stop without further attention to the electric brake, since the control of both the electric and air is by means of the regular air-brake control valve. Under such conditions the electric braking controller notches automatically under the control of the air, the maximum electric braking being limited by the kilowatt and current limit relays previously referred to. The air pressure is held off the driver brake cylinders by suitable suppression valves as pointed out above, but is admitted to the brake cylinders of guiding axles and the remainder of the train.

The setting of the kilowatt and current-limit relays is increased if the brake pressure in the pipe which supplies air to the brake cylinders is raised above 45 pounds per square inch. The setting of these relays is graduated in this manner up to 100 pounds per square inch. This permits the use of higher electric braking rates on streamlined trains where cylinder pressures as high as 100 pounds per square inch are used. This change in setting is effective in maintaining the electric braking on the drivers at a value only slightly less than that which would be obtained with the normal air brake over the range in pressure involved. The increase in kilowatt and current setting is permitted since the use of the air brakes in combination with the electric brakes means that the train must be slowing down even on the heaviest grades, and, therefore, that the motors can be subjected to these high braking rates for the relatively short periods involved.

Automatic blending of the air and electric brake, when both are used, is accomplished by means of suppression valves in combination with a pneumatic blending control incorporated in the air brake system. The arrangement is such that the air brakes can be suppressed only in the event the electric brake exceeds a predetermined minimum. Air brakes on the drivers are automatically applied at any time electric braking is lost. Air brakes are also gradually applied automatically as the electric braking fades out at very low speeds just preceding a stop.

A cutout button is provided which permits the operator to cut out the automatic feature of the electric brake and allows him to dispense with the automatic control of the electric brake from the air-brake control valve. This cutout button does not interfere with the use of the manual control of the electric brake in combination with the air brakes. By controlling the air and electric brakes separately, the amount of braking on the locomotive can be reduced to any desired value to permit control of slack during a stop.

When descending long grades it is possible to establish electric braking manually to hold some desired speed and apply the air brake for slow downs for curves without disturbing the electric brake handle. When the air brake is applied under this condition the electric brake will advance automatically to assist the air brakes in slowing down the train. It will return to the speed setting used prior to the air application, without attention from the operator when the air brakes are released.

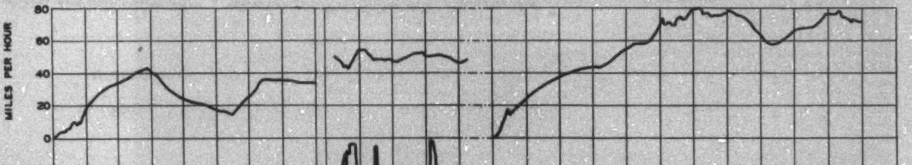


Figure 17. Graphical records of kilowatts, amperes, and speed. Main-line run

Every effort has been made to provide the greatest flexibility possible in the control of the electric brake, both separately and in combination with air, so that full advantage can be taken of this new type of braking equipment under all operating conditions.

Electrical Couplers

The streamlined trains of the Union Pacific system are equipped with three separate three-phase train lines throughout the train. The rear end of each unit of the locomotive is, therefore, equipped with three three-phase couplers, one of which is illustrated in figure 15. These are a new design of knife-blade type arranged especially for easy assembly and having a continuous rating of 450 amperes per phase. Threaded knobs assist in inserting or removing the jumpers, and act as a lock when the jumper is in place, or as a cover lock when the jumper is removed. One of these couplers is provided at the head end of each unit. If two units are operating in multiple, one train line is supplied from the alternator of the first unit, and the other two from the alternator of the second unit. This arrangement permits supplying three-phase power from one locomotive to the other for use when starting the plant, or for charging the batteries of both units with only one plant running. The alternators on the two units are never paralleled.

A new-design 24-point control coupler, figure 16 handles the train-line wires of the 130-volt control circuits, and the electrical air brake control, telephone, and special signal wires for streamlined trains. Two of these couplers are installed at each end and give a maximum of 48 control train lines in an extremely small space. Locking knobs similar to those on the three-phase couplers assist in inserting and removing the jumpers.

One two-point 100-ampere coupler is provided on the ends of each unit for the 64-volt battery bus line standard on Union Pacific streamliners. The baggage-car battery is charged from the 64-volt generator on the locomotive through this train line.

Multiple-Unit Operation

For the first time in the history of railroading two steam locomotives are completely controlled from the operating position in the cab of either locomotive. This multiple-unit control system, which is similar to that used on electric locomotives, is completely electric and makes use of conventional train lines connected between units through train-line jumpers. The train lines are energized in the proper sequence to operate the contactors which establish the various power-circuit combinations required for motoring, electric braking, and for controlling the metadyne exciter.

The loading of each power unit is independently maintained by individual turbine-speed control elements to insure maximum available total output when required. Motor circuit transitions are automatic and are controlled independently on each unit so that they take place at the proper speed to match the output.

When using electric braking, the multiple-unit circuits are energized in proper sequence by the notching of a single controller at the operating position and this notching is supervised by relays and protective equipment of each unit. This means that the kilowatt and current rating of the individual units cannot be exceeded and that the protective equipment of both is fully effective.

All visual indicators at the operator's position function normally when using multiple-unit control and respond to corresponding operating conditions of both units during acceleration and braking.

To obtain flexibility under unusual operating conditions cutout and change-over switches have been provided. By throwing a single switch either unit may be made inoperative and full control of the remaining unit from either operating position retained.

The motor cutout arrangement is of the type used quite generally on electric locomotives. The arrangement is sufficiently flexible so that any pair of motors or a single generator of either power unit may be cut out and still permit automatic control of the power plant and automatic transitions. This arrangement insures maximum available output in the event it is necessary to cut out motors.

With the multiple-unit control system the same flexibility is available regardless of whether the locomotive consists of a single power unit or two power units operating in multiple.

Train Control

The locomotives are equipped with three separate train-control systems to conform to the different lines over which they will operate. Power is obtained from a motor generator set driven from a 130-volt d-c motor and supplying 32 volts held constant by a voltage regulator.

A two-indication continuous cab signal system with two-speed control is provided for operation over the lines of the Chicago and North Western Railway. A two-indication continuous-cab-signal system with whistle and acknowledging feature is included for use on the lines of the Union Pacific Railroad. An intermittent magnetic inductive automatic stop system is provided for use on the Southern Pacific.

Discussion

For discussion, see page 1082.

Some Practical Measuring Devices

LLOYD F. HUNT
FELLOW AIEE

IN the operation of a large utility very often it is desirable to make practical measurements which are not generally obtainable from the usual manufactured devices. It therefore becomes necessary to make some unusual devices to record information that will assist in the operation of a large system. This discussion will present some devices that have proved very useful for years, and some more recent ones that are being tried out.

Travel Recorder

The Southern California Edison Company, Ltd., has made 116 short-circuit tests on their 220-kv system for determining the operation characteristics of various types of oil circuit breakers. The normal evolution in making these tests brought out the fact that one of the most important facts was not shown on the oscillograms. This was the actual position of the crosshead during any position of the oil-switch stroke. In order to make an accurate record on the oscillograph of this stroke, a simple recording transmitting device was made to use in conjunction with the oscillograph.

Figure 1. Oscillogram showing travel-recorder record

Figure 1 shows an oscillogram of an oil-switch test. The travel record is shown by the stair steps. Going from left to right, the stair steps go up four steps, then repeat. This gives an accurate position of the crossheads on the closing stroke. Each change in steps or dots indicates one-fourth inch in crosshead travel.

This oscillogram is a record of an OCO operation, so the stair steps go up when the crosshead is traveling up, and go down when the crosshead is traveling down. It will be noticed that every seven inches of travel the dot is one step lower than the usual one for this position. This point is used to indicate when the oil-switch contacts physically close and open. The device is so set to give this position before each set of tests by actually checking the closing of switch contacts with low voltage. With this accurate method of determining when the contacts are closed, it is possible to tell very accurately when the switch prestrikes on closing, and how long it arcs in opening. From this oscillogram it can be seen that this switch prestruck exactly one-quarter inch, and arced exactly seven-eighths inch on opening.

The construction of the transmitting device is very simple, as shown by figure 2. It consists of a small motor commutator with 28 bars. Every fourth bar is connected together, as shown by figure 3. The commutator is stationary, having a light double-contact brush rotating around the commutator. The travel device is connected to the crosshead by means of a small music wire which is wound and unwound on a drum that drives the brushes (one revolution of the drum equals seven inches of motion). The music wire is kept under considerable tension by a large clock spring. The inertia of the moving parts of this device has been kept to a minimum.

This device has been used on our last three sets of tests, and has been the means of gathering very important information regarding the behavior of oil-switch travels.

Another interesting circuit used on the oscillograph was that of recording trip-coil voltage and current. In some of the tests, it was necessary to give the point where the tripping relay closed, and in some cases the oil switch prestruck before the trip-coil auxiliary switch closed. Since all the available elements of the oscillograph were used for various records, it was necessary to devise this method of obtaining trip voltage and current on one element. Figure 4 shows the schematic of this connection. When relay contacts close, definite current flows through resistor *R*2, causing a deflection; then if *A* is closed at the time the relay closes contacts, the oscillograph measures the voltage drop across the shunt. Figure 5*a* is a trace of a normal oscillograph of trip-coil voltage and current. Figure 5*b* is a trace of an oscillograph where the relay closes contacts and a period later the auxiliary switch causing trip-coil current to flow.

Voltage Indication

To facilitate operation of a high-voltage transmission system, means for indicating at each end of a line whether it is

---

Paper 39-125, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted April 14, 1939; made available for preprinting May 18, 1939; released for final publication August 16, 1939.

Lloyd F. Hunt is protection engineer, Southern California Edison Company, Ltd., Los Angeles.

"hot" or not are very desirable. The cost of potential transformers for the purpose is generally so high that other means have been sought. One of these is by using a very sensitive a-c instrument shunted across the ground insulator of a string, as shown in figure 6. The instrument is a 0 to 100-microampere meter with an adjusting rheostat of 15,000 ohms. This is a good "hot" line indicator, but the indication will vary with the humidity of the air. The scale can be marked in normal voltage of line and with the adjusting rheostat kept at approximate correct reading. In service this type of instrument has proved itself very useful. In some cases the two leads are in lead-covered cable for some 400 feet.

In the case of the original General Electric bushing with low-voltage capacitance taps, it was necessary to use a one-tube amplifier to get good voltage readings. With the new a-c microammeters now available it is possible to have a direct-reading voltmeter. It is only necessary to have a 0–300 microammeter connected direct to the capacitor tap. To adjust the meter, a suitable rheostat is connected in parallel with the instrument.

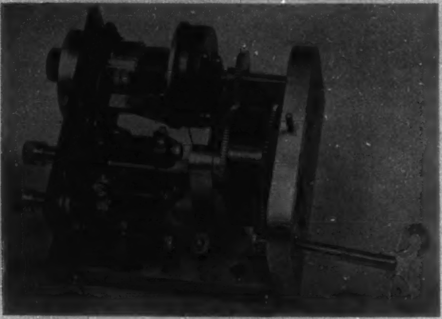

Figure 2. Travel-recording transmitter

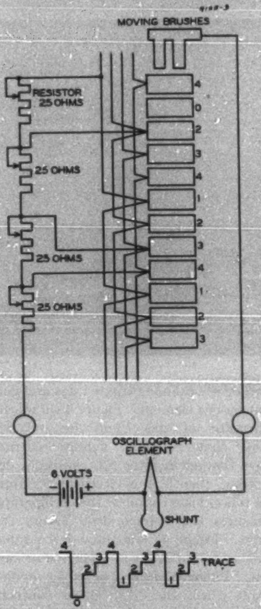

Figure 3. Layout of travel-recording transmitter

Disturbance Recorders

In order to study short-circuit conditions on a large transmission system, it is necessary to have high-speed recording devices. The Edison company has four oscillographs, six Hall recorders, and eleven disturbance recorders connected to the transmission system at the various important stations. These instruments operate to give records for system study of most all transmission faults. Most faults have a normal clearance, so the most value these records have is when the occasional abnormal clearance occurs.

The oscillograph and Hall-recorder films must be developed and calibrated before the information is available. The disturbance recorder is a high-speed device that has a motor running continuously, that engages the paper drive by means of a clutch that is operated by fault-detecting relays. At the same instant, a spark coil is energized that punctures the paper to give the trace of measuring device.

These instruments are made in various forms; one was made from a normal five-ampere recording ammeter by stiffening the restraining spring so it took 50 amperes full scale. This gives the instrument 100 times the torque it had originally. With this energy the instrument deflection is exceedingly rapid, being in the order of a few cycles. In order to damp the instrument while recording, it is necessary to use very heavy damping by means of an electromagnet. The speed of charts for the various recorders ranges from two to five inches per second.

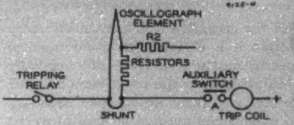

Figure 4. Oscillograph connections for measuring tripping voltage and current

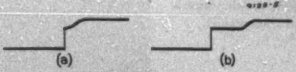

Figure 5. Oscillograph traces of tripping voltage and current

These ammeter-type disturbance recorders are being used to determine the length and magnitude of ground faults on the 220-kv system. The readings from the various locations of the system are immediately available, and enable the dispatchers to determine the approximate location of the fault.

Figure 7 shows the disturbance recorder installed at Chino substation, the receiving station for Boulder power. This instrument records ground current, voltage, and frequency. Figure 8 shows

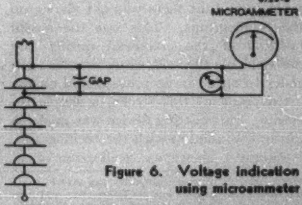

Figure 6. Voltage indication using microammeter

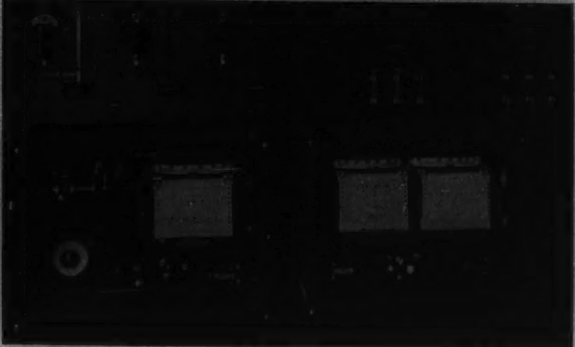

Figure 7. Three-element disturbance recorder

the auxiliary devices necessary for operating the disturbance recorder. Figure 9 gives the schematic connections of the various parts.

Figure 8. Disturbance-recorder auxiliary

The operation of this recorder can be easily followed by referring to figures 7, 8, and 9. The left element is for measuring 66-kv and 220-kv ground currents. The current transformers are in the neutral of the two banks—one on the 66 kv and the other on the 220 kv. In the case of the 220 kv, the current measured is the ground-fault-neutralizer current. Each of the neutral-current-transformer secondaries is connected to an *AX* relay and transformer. The transformers are so connected as to indicate on one element. The current element consists of a large D'Arsonval d-c element shunted heavily for damping supplied from the secondary of the transformers through a full-wave rectifier. The permanent magnet of the D'Arsonval unit is replaced by a saturating electromagnet to give the maximum flux possible. The end of the needle is made of tungsten to prevent burning from the spark required to puncture the paper.

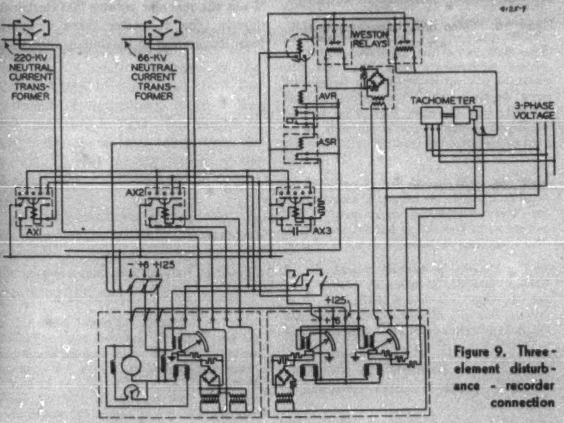

Figure 9. Three-element disturbance-recorder connection

The *AX*1 and *AX*2 relays are instantaneous relays, and the duration of the fault can be accurately measured by precalibrating the recorder by passing through it a given current for a given length of time. In most actual cases, the recorders have checked the duration of fault as recorded by the oscillograph within a couple of cycles.

The center element is similar in construction, but electrically it is a voltmeter. The right element is a frequency recorder. Both of these elements are normally energized and give indication of normal voltage and frequency. In the case of abnormal voltage, a sensitive Weston relay is used to close contact. This relay operates an auxiliary relay, which in turn energizes a vibrating relay *AVR*. The vibrating relay energizes time-delay contact-opening relay *ASR*, which in turn energizes relay *AX*3. When *AX*3 is energized, the clutch of the disturbance recorder is engaged to start the chart, and the spark coils for voltage and frequency charts are energized to puncture paper for the trace of the abnormal condition.

Since the voltage may swing to normal, then back to abnormal, the vibrating relay is set to continue the chart trace from five to ten seconds.

The frequency indication is obtained by using a small three-phase synchronous motor driving a tachometer. The voltage from the tachometer is proportional to the frequency. The movement has a suppressed zero, and records 40 to 70 cycles. The normal frequency is 50 cycles. Should high or low frequency occur, a sensitive relay is used to close contact under these conditions to start the same series of relays as used on the voltage recording. The continuing of recording upon return of normal frequency has proved very important. In many cases the frequency will change from one abnormal condition to the other. The chart should continue during this period. Many very accurate records of voltage and frequency have been obtained during system disturbances. Figure 10 gives a photograph of a voltage chart during a short circuit.

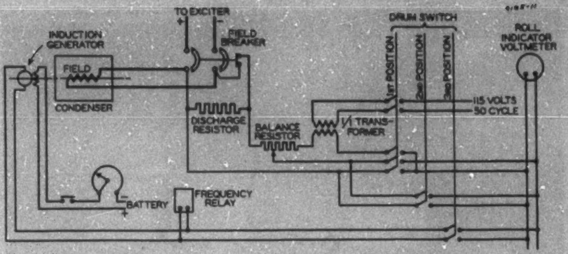

Figure 11. Wiring diagram of condenser roll indicator

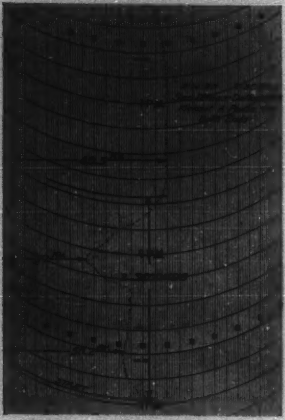

Figure 10. Chino disturbance-recorder voltage chart

Synchronous-Condenser Roll Indicator

At the new Chino substation, the 50,000-kva hydrogen-cooled synchronous condenser is an outdoor type. The operating room is approximately 150 feet from the condenser. When the condenser is started, a remote device for giving the operator an indication of the fact that the condenser is starting or not is necessary. A simple and effective device called the roll indicator is shown by figure 11. The indicator is a normal 0–150-volt a-c instrument. It is so connected that it measures the difference of a 50-cycle voltage produced by an auxiliary transformer and the induced voltage produced across the condenser field-discharge resistor. As soon as the condenser starts rolling, the voltmeter needle moves. When the machine rotates 360 electrical degrees, the voltmeter takes a swing from its position to maximum, then to a minimum back to its starting point. This action may be the reverse from this according to the actual phase location of the field when the machine is started. As the machine speeds up, this cycle of indication speeds up to a point when the voltmeter can no longer follow the fluctuations. At this point the fixed 50 cycles is removed from the instrument, and only the voltage drop across the discharge resistor is measured. As the machine comes into synchronism, the voltmeter will read the induced voltage in the field, and when nearly in step the meter will give a swinging indication. When the machine pulls into step, the voltmeter will indicate no swinging and zero on the dial. The voltmeter is then switched over to read voltage of the small shaft-induction generator which gives an indication of condenser speed.

Temperature Survey of the United States

J. J. SMITH
ASSOCIATE AIEE

H. W. TENNEY
MEMBER AIEE

IN establishing the rating of electrical apparatus there are many factors involved. The maximum temperature reached by any part of the insulation is one of these. However, the relationship of temperature to rating is a complex function and the rating cannot be considered as a function of temperature alone.

In order to arrive at a rational system of rating, it is necessary to have standard rating specifications for various classes of apparatus, according to which all ratings in each class are established. In general these specifications give an allowable temperature range in terms of temperature rise. The temperature range must be referred to some maximum allowable temperature base. This base, from a rating standpoint, is called the ambient temperature. From the point of view of practical consideration the ambient temperature selected should reasonably fall in the range of normal conditions. At the same time it should not be too remote from readily obtainable temperatures, at which temperature tests may be conducted.

The selection of 40 degrees centigrade as a possible maximum temperature in the above procedure, seems to have been a fortunate one in nearly all cases. No difficulty is encountered with this basis of rating, even in the occasional cases where the actual ambient conditions are excessive, for the proper use of equipment under such circumstances should be handled as an application problem. It must be borne in mind, however, that the modification of the allowable temperature rise is not a direct function of the ambient. This means that a motor used in an ambient 10 degrees centigrade lower than usual cannot necessarily be used at 10 degrees higher temperature rise.

In order to obtain authoritative information on atmospheric temperature in all parts of the country, at all seasons of the year, and for long periods, the records of the United States Weather Bureau were consulted. Through the courtesy of the Weather Bureau, analyses of automatic thermograph charts for a limited number of stations were made. Studies were made of these data and of data taken from the reports of the Weather Bureau to suggest suitable forms in which they might be useful to engineers.

This paper contains the following information:

A—Summary of sources of weather data (see appendix I)

B—Temperature data for many well-distributed locations throughout the country

C—Data on electric motors in industrial uses and the power generated, arranged according to geographic locations

Temperature Data Presented in This Paper

The temperature data presented in this paper in items 1 to 3 have been taken from the "Climatic Summary of the United States" by the United States Department of Agriculture, Weather Bureau, published in 1930. For items 6, 7, and 8 data have been taken from the annual "Report of the Chief of the Weather Bureau" back to 1892 (see table I).

All temperatures reported by the Weather Bureau are from thermometers suspended in thermometer houses. The thermometers are not exposed to the direct rays of the sun.

1. *Annual Average Temperature.* The annual average temperature represents the average of the daily minimum and maximum readings for each day during the entire period of record. This period is about 50 years, so each annual average represents approximately 36,500 individual readings (52.8 degrees Fahrenheit for the entire United States).

2. *Average Yearly Variation of the Monthly Average Temperature.* This variation was taken as the difference between the highest average monthly temperature and the lowest average monthly temperature. The highest average temperature is not the highest average temperature on record but it is the average of the average temperatures for that month over the entire period during which records have been kept. (43.4 degrees Fahrenheit for the entire United States.)

3. *Average Daily Variation of Hourly Temperatures.* The average daily variation is taken as the difference between the average of the daily maxima and the average of the daily minima for the entire record period. This does not represent the true average daily variation to be expected in either the winter or the summer, because data from the Weather Bureau show that in most locations the winter daily variation is four to five degrees less than the summer daily variation. However, by using an average value, there will be an error of only about two degrees in either winter or summer, and it will be fairly accurate for the greatest portion of the time. (20 degrees Fahrenheit average for the entire United States.)

4. *The Absolute Maximum Recorded.* This temperature is as its name indicates, the maximum temperature recorded at that station at any time during the record period, see figure 1. (The highest temperature ever recorded at a Weather Bureau Station was 134 degrees Fahrenheit, and the average of the maxima for the entire United States is 104.7 degrees Fahrenheit.)

5. *The Absolute Minimum Ever Recorded.* This temperature is just as its name indicates, the minimum temperature recorded at a station at any time during the record period. (The lowest temperature ever recorded at a Weather Bureau station was −57 degrees Fahrenheit and the average of the minima for the entire United States is −18.6 degrees Fahrenheit.)

6. *Average Number of Days per Year Temperature Exceeded 90 Degrees Fahrenheit.* From the annual "Report of the Chief of the Weather Bureau" for the years 1892 to 1936 were taken the number of days each year the temperature exceeded 90 degrees Fahrenheit and averaged for 179 Weather Bureau stations. These averages were plotted on a map, figure 2, and climatic bands were developed. These averages for representative stations are recorded as part of table I.

7. *Maximum Number of Days per Year Temperature Exceeded 90 Degrees Fahrenheit.* These values were obtained from the reports mentioned in (6) and are recorded in table I for representative stations.

8. *Minimum Number of Days per Year Temperature Exceeded 90 Degrees Fahrenheit.* These values were also obtained from the reports mentioned in (6) and are recorded in table I for representative stations.

Duration of Elevated Ambient Temperatures

Consideration will first be given to certain limiting conditions of temperature. From a survey of the whole country of the highest temperatures ever observed, made by the United States Weather Bureau, the following results were obtained:

Paper 39-141, recommended by the AIEE committees on electrical machinery and industrial power applications, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted April 12, 1939; made available for preprinting May 18, 1939; released for final publication September 6, 1939.

J. J. SMITH is assistant engineer, general engineering laboratory, General Electric Company, Schenectady, N. Y.; H. W. TENNEY is manager of the engineering laboratories and standards department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

6. For all numbered references, see list at end of paper.

Maximum Temperatures Never Exceeded (Deg F)	Percentage of Area of the United States Affected
100	10.8
105	35.2
110	73.1
115	95.0

Note: Temperature in only 5 per cent of the area of the country has ever exceeded 115 degrees Fahrenheit.

To obtain correlation of monthly temperatures throughout the country, temperature data from 23 stations were tabulated and averaged. Figure 3 is a composite graph showing the absolute station maximum and minimum, the average of the average monthly maximum, the average of the average daily maximum, the average of the average monthly temperature, the average of the average daily minimum and the average of the average monthly minimum.

All of the temperature curves are cyclic in character and change in an orderly way from season to season. The maximum temperature is usually recorded in July or August. The variation of the maximum and minimum from the average is a characteristic of the climate at the 23 stations and may cover extreme ranges in some cases.

The information from which the curves were derived was obtained from averages over a period of time ranging from 15 to 75 years. The 23 stations are representative of the extremes of climate and while they do not indicate the maximum that has ever been reached they are representative of the extremes in the inhabitable areas of the United States.

Consideration of the maximum temperatures ever reached over the country, as well as of the average conditions for 23 stations, representative of the whole country, gives some very valuable general information. However, cognizance must be taken of the fact that the length of time the higher ambient temperatures are sustained is responsible for insulation deterioration. As a basis for this study an analysis was made of information compiled by the Weather Bureau[6] showing the number of days per year the temperature exceeds 90 degrees Fahrenheit for 179 stations over the country. An average of data for the years 1892 to 1936 was obtained and the numerical values were spotted on a map. From this map, figure 2 was developed on which climatic bands are shown. Mark 10 indicates that all territory above this has had ten days or less per year in which the temperature has exceeded 90 degrees Fahrenheit. It will be noted from this map that taking all area above climatic band marked 60, practically all of the country in which there is a dense motor population is included.

From the Weather Bureau were obtained the number of hours per day the temperature remained above 90 for each day the temperature exceeded 90 degrees Fahrenheit for eight selected stations for a period of five years (1934 to 1938). These data were plotted and are shown in figure 4. With this curve it becomes

Figure 2. Map of average number of days per year in which temperature exceeded 90 degrees Fahrenheit

possible to determine within reasonable limits the number of hours per year the temperature exceeds 90 degrees Fahrenheit, if the number of days per year on which the temperature exceeded 90 degress is known. For instance, it is found that where the temperature is above 90 degrees for 60 days—the temperature will on the average be above 90 degrees for approximately 410 hours. Figure 5 is a curve showing the relationship between the average number of hours per year the temperature exceeds 105 degrees Fahrenheit against the average number of days per year in which the temperature exceeds 105 degrees. If the curve were based on data covering a longer period the figures may be subject to some modification. This study of days exceeding a certain temperature may be continued at temperatures higher and lower than 90 degrees. Correlation of the resulting data for any one locality would show the average time the temperature exceeded any given temperature in the space of a year. From a series of such curves the per cent time that the temperature exceeded a given value in any part of the country could be obtained. Additional work, however, is required to obtain these results.

Probability of Occurrence of Temperature Extremes

Quite often it is necessary to design electrical equipment to withstand the maximum or minimum temperature to be encountered in a given locality. One such instance is the design of air-cooled rectifiers using an intermediate fluid between the air and the rectifier. In these cases it is difficult to decide what maxima and minima are to be expected. Certainly the highest and lowest on record for a period of 50 to 100 years cannot be expected more often than once in 50 or 60 years. After a brief study of the frequency of occurrence of extremes in representative locations the following frequency of occurrence was found to be approximately applicable:

1. The maximum temperature to be expected once in ten years is three degrees Fahrenheit below the maximum recorded to date.
2. The maximum temperature to be expected once in five years is 5 degrees Fahrenheit below the maximum recorded to date.
3. The maximum temperature to be expected every year will exceed a temperature ten degrees Fahrenheit below the maximum recorded to date.
4. The minimum temperature to be expected once in ten years is five degrees Fahrenheit above the minimum recorded to date.
5. The minimum temperature to be expected once in five years is six degrees Fahrenheit above the minimum to date.
6. The minimum to be expected every year will be lower than a temperature 25 degrees Fahrenheit above the minimum recorded to date.

These figures are only approximate and need to be interpreted with judgment. In the coastal regions, such as Florida and the west coast, the variations will not be so great. Likewise in the great plains region from Ohio to the Dakotas the variation will not be so great. Some of the eastern seaboard region has variations much greater than given in these figures. These values are only suggested as a benchmark so that the actual maximum and minimum recorded temperatures can be properly used.

In using maximum or minimum temperatures the duration of these temperatures should be considered. These temperatures are almost always of short duration, lasting at most a period of three or four hours and occurring only about once a year. Generally they are local

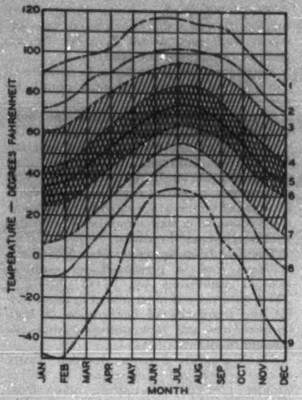

Figure 3. Composite temperature chart—23 Weather Bureau stations (over periods ranging from 15 to 75 years)

1. Absolute maximum temperature
9. Absolute minimum temperature

(These two curves show maximum and minimum temperatures, respectively, for each month of the year, which were ever recorded at any of the 23 Weather Bureau stations during period of record)

2. Mean of absolute monthly maximum temperatures
8. Mean of absolute monthly minimum temperatures

(These curves were obtained by averaging the absolute maximum and minimum temperatures, respectively, which were ever recorded at each station for each calendar month during the period of record)

The remaining curves were obtained by calculating the mean for the 23 Weather Bureau stations from the average data for each station for the period of record

3. Mean of the average monthly maximum temperature
4. Mean of the average daily maximum temperature
5. Mean of the average monthly temperature
6. Mean of the average daily minimum temperature
7. Mean of the average monthly minimum temperature

phenomena, seldom being approached within ten degrees at locations 50 miles distant. The time-temperature lag of most equipment is great enough to carry through these short peaks of either maximum or minimum temperature.

The estimates of the probable occurrence of high temperatures are more accurate than the estimates of the probable occurrence of low temperatures. That is, most localities will show high temperatures occurring approximately as given by these values though the low temperatures sometimes vary widely from the values given.

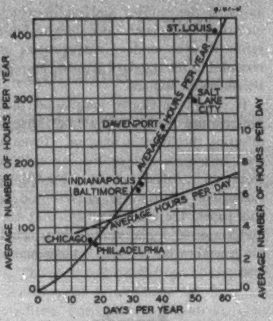

Figure 4. Curve of average number of hours per year and average number of hours per day versus average number of days per year temperature exceeds 90 degrees Fahrenheit (five-year period 1934 to 1938)

Distribution of Electrical Equipment

Complete information on the exact distribution and use of electrical equipment is not available. However, information is available[12,14,15] which will give an indication what the actual total distribution of electrical equipment is. Some of the available data have been summarized in tables II and III. Table II shows the distribution of electric motors in use or available for use in manufacturing and printing establishments at the close of the year 1929. This

* Data from "Central Electric Light and Power Stations", United States Department of Commerce, Bureau of Census, 1932.

information is presented by states according to the number of motors and the total horsepower rating. These figures represent about $5^{1}/_{3}$ million motors in the United States with an aggregate horsepower rating of 35 million.

Table III shows the current generated in the United States according to geographic districts. It represented about 79 billion kilowatt-hours in 1932. This has increased[15] to 109 billion kilowatt-hours in 1938.

An examination of these tables will show that the majority of motors and power used is located in the district from Chicago east to the coast and up through the New England states and in another district on the Pacific Coast. The kilowatt-hours generated in these districts is just about of the same proportion.

If the total area where the temperature exceeds 90 degrees Fahrenheit for more than 60 days in a year in figure 4 is taken and it is assumed that the motor population as given in table II for each state is uniformly distributed over the state, the motor horsepower in the areas where the temperature exceeds 90 degrees Fahrenheit more than 60 days per year is less than five per cent of the total installed motor horsepower of the country. From figure 6 it is found that where the temperature exceeds 90 degrees on an average of 60 days per year, the temperature remains about 90 degrees for 6.5 hours per day or 390 hours per year, though in some of these places even this time is considerably less.

The present AIEE standards assume a normal design ambient of 40 degrees centigrade (104 degrees Fahrenheit). Study of the maximum temperature recorded at all points in the country shows that 104 degrees Fahrenheit is the average of these maxima although an absolute maximum of 134 degrees Fahrenheit has been recorded. If the average maximum recorded is to be the basis of the standards for design, 40 degrees centigrade is certainly the best figure.

Conclusions

In establishing ratings on electrical apparatus the problem is broadly one of selecting a reference temperature which satisfies the majority of applications. From the review of actual temperature conditions of the United States, it is seen that in most locations there is a small margin between the ambient of 40 degrees centigrade (104 degrees Fahrenheit) and the maximum outdoor temperatures. It must be clearly borne in mind, however, that this paper takes no cognizance of the outdoor ambient in which electrical equipment may operate, but refers only to outdoor temperatures as recorded in the standard Weather Bureau thermometer stations.

It should be clearly understood that temperature is only one of the factors affecting the life of a machine. From a vast experience in operation, as well as from an analysis of the conditions throughout the country as presented in this paper, the indications are that the ambient of 40 degrees centigrade selected for general rating purposes is a reasonable one.

Appendix

Summary of Existing Weather Data

In beginning a survey of the weather conditions existing throughout the United States, it was first necessary to determine the sources of information available and the nature of the information contained in these sources. The best sources of available information are:

1. "Climatic Summary of the United States," by the United States Department of Agriculture, Weather Bureau, published in 1930.

2. "Climatological Data for the United States by Sections," published monthly by the United States Department of Agriculture, Weather Bureau.

3. "Climatological Data for the United States by Sections," published yearly by the United States Department of Agriculture, Weather Bureau.

4. "Climatology of the United States," Bulletin *Q*, United States Department of Agriculture, by A. J. Henry, published in 1905.

5. "Monthly Summary of Temperature and Dew Points," published by the aerological division of the United States Weather Bureau.

6. "Yearly Reports of Chief of the Weather Bureau" from 1892 to date ("Meteorological Year Book" since 1936).

7. "Atlas of American Agriculture," Part II—Climate.

8. Automatic thermograph charts on file at the Weather Bureau in Washington, D. C.

Source number 1 contains the most data in the best form for use in this paper. For the United States Weather Bureau stations, numbering approximately 250 throughout the country, it contains detailed information of the averages over the last 50 years (approximately). The information contained is summarized as follows:

1. *Temperature*. Highest monthly average on record for any one year, lowest monthly average on record for any one year, for each month, season, and entire year—
Average temperature
Average of the maxima
Absolute maximum
Average of the minima
Absolute minimum

2. *Sunshine*. For each month, season, and entire year
Average hours with sunshine
Percentage of possible

3. *Miscellaneous Items*
Average number of days with maximum temperature of 90 degrees Fahrenheit or above
Average number of days with minimum temperature of 32 degrees Fahrenheit or below
Average number of days with minimum temperature of 0 degrees Fahrenheit or below
Average number of days with dense fog
Maximum precipitation recorded in periods of 5, 10, 15, etc., minutes up to 120 minutes

The information contained in source number 2 represents the annual monthly report from each of the Weather Bureau stations throughout the country.

Source number 3 contains summaries of the information presented each month by source number 2.

Source number 4 is perhaps the most complete collection and presentation of the climatology of the United States that has been made. However, it represents only the information available up to 1905. This information in general is the result of about 25 years of temperature records. The more recent data, as in source number 1, contains another 25 years of records.

The data from source number 5 has been analyzed and is presented for summer weather conditions by J. C. Albright. These data proved most useful in determining the frequency of occurrence of high temperatures and dew points during the summer months.

Source number 6 gives detailed yearly reports which are summarized in source number 1. The information taken from these reports is:

1. Number of days per year for each year since 1891 the temperature has exceeded 90 degrees Fahrenheit

(*a*). Average number of days per year the temperature exceeded 90 degrees Fahrenheit for 45 years for most of 179 stations.

(*b*). Maximum number of days the temperature has exceeded 90 degrees Fahrenheit in one year.

(*c*). Minimum number of days the temperature has exceeded 90 degrees Fahrenheit in one year.

Source number 7 gives temperature graphs for 23 stations. From these data a composite temperature graph was drawn showing:

1. Absolute station maximum temperature
2. Absolute station minimum temperature
3. Average of absolute monthly maximum temperature—23 stations
4. Average of average monthly maximum temperature—23 stations
5. Average of average daily maximum temperature—23 stations
6. Average of average monthly temperature—23 stations
7. Average of average daily minimum temperature—23 stations
8. Average of average monthly minimum temperature—23 stations
9. Average of absolute monthly minimum temperature—23 stations

These data are for a period of approximately 42 years.

From source number 8 the number of days and the number of hours of each day the temperature exceeded 90 degrees Fahrenheit was obtained for a five-year period.

Similar data were obtained for 105 degrees Fahrenheit.

The same information as given by items 1 and 2 above is given for 20 to 50 small stations located in each of these districts as well as for the two or three regular Weather Bureau stations. These data are tabulated giving the annual averages for temperatures and the actual monthly precipitation for each year on record.

Discussion

For discussion, see page 1090.

Mingled Hydro and Steam Power Production in California—Past, Present, and Future

A. H. MARKWART

THE development in the United States of the central-station industry from its inception in San Francisco in 1879 and in New York in 1882, to the present, has been made in two broad phases. The initial or pioneer phase includes the first isolated steam-electric plants serving lighting customers, followed by small hydroelectric plants serving nearby customers and later (in Oregon in 1889) with the development of higher transmission voltages, serving customers remote from the generating plants. Mingled steam and hydro power was inaugurated in 1895 when the Folsom hydroelectric plant was connected to a steam-electric plant at Sacramento. In 1899, also at Sacramento, and again in the San Francisco Bay region in 1902, distant hydroelectric plants were connected with each other and with local steam plants. It may be said that these interconnections of remote hydro supplies with steam-electric plants culminated the initial phase.

The second phase was one of extensive development substantially all of which resulted from private initiative. The technique of production, transmission, distribution, and utilization of electric power was perfected and the field for utilization was broadened. The size of generating units became larger, efficiencies increased, transmission voltages and capacity were raised, more interconnections were made, and in the desire to derive all of the benefits resulting from complete co-ordination of all facilities serving a common market, the several properties were merged, first physically and later corporately, into integrated systems. The properties throughout the country now are well interconnected physically although something still remains to be done in so far as corporate integration is concerned.

During the last decade, a new idea has been advanced which contradicts that which has governed the central-station industry, namely, one of orderly development. Federal reservoir projects have been initiated throughout the nation, primarily to improve navigation, to control floods, and to supply water for irrigation—and, incidentally, to generate power. The generation of power, while incidental to the primary purposes, becomes a factor of major importance if revenue is to be provided to defray the cost of such projects. Projects of this character had been constructed by local private and public interests in California and in connection with Bureau of Reclamation projects in other states, but they were relatively small in size and the marketing of the power throughout the then existing agencies, did not present a serious problem.

The first of the large Federal multipurpose projects was the Colorado River development, which was thoroughly investigated in all of its phases and particularly with reference to the sufficiency of the revenue from the sale of power and water to reimburse the Federal Government for expenditures on that project. Firm long-time contracts for the sale of power and water were negotiated before work actually began.

When in 1933 the Federal administration in order to restore economic prosperity believed it necessary to expend Federal moneys on large projects throughout the country, it was inspired, possibly because of the success which accompanied the Boulder Canyon project, to launch a number of similar projects, generally without thorough investigation of potential power markets and in all cases with no arrangement for income to liquidate any substantial part of the cost. These projects are introducing large amounts of power in some regions and are creating major problems with respect to absorption. These projects, arising in what might be termed the third phase of the development of the industry, are closely related to its future progress.

It is proposed to discuss herein, the progress of the industry in California in the three phases of development just outlined and to attempt to forecast in a general manner what generating facilities will be required in the future.

Historical Beginnings—The Pioneer Phase of Development

It is generally stated that the first central-station plant in the United States was the Pearl Street steam-electric plant constructed in New York in 1882. Actually, however, this plant was preceded by a small steam-electric station in San Francisco constructed in 1879 by the California Electric Light Company, one of the many predecessor companies of the Pacific Gas and Electric Company. The demand for electric energy was germinated in this plant so beginning about

---

Paper 39-119, recommended by the AIEE committee on power generation, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted April 26, 1939; made available for preprinting May 22, 1939; released for final publication September 5, 1939.

A. H. Markwart was vice-president in charge of engineering, Pacific Gas and Electric Company, San Francisco, Calif., at the time of his death, January 25, 1940.

1885, small generating units were installed in San Francisco and Oakland and by 1895 a total of nearly 6,000 kva had been installed.

The first hydroelectric plant in the world constructed to serve a distant demand was at Oregon City in 1889, the power being transmitted at 4 kv some 13 miles to Portland. The first hydroelectric plant in California was constructed at San Bernardino in 1887 and it served a load in its immediate vicinity. This was followed in 1891 by the 120-kva Pomona plant of San Antonio Light and Power Company which was the first hydroelectric plant in California constructed to transmit power at high voltage (10,000 volts) to distant loads (14 miles to Pomona and 28 miles to San Bernardino). The first hydroelectric plant in northern California was the Folsom plant, constructed in 1895 and still in operation—1,500 kva, transmitting power at 11,000 volts some 22 miles to Sacramento.

Hydroelectric development in northern California expanded rapidly owing to the presence of storage reservoirs and canal systems which had been constructed to serve the hydraulic mines in the Sierra Nevada mountains and foothills. Hydraulic-mining operations in this region declined rapidly after the famous Sawyer decree in 1884, when the United States Circuit Court issued an order restraining the North Bloomfield Mining Company from discharging debris into the streams. Mine after mine was closed by injunction and many of the storage reservoirs and the canals would have been rendered permanently obsolete except for the new type of power which could be generated from falling water and transmitted to points of use in distant towns. The Pelton water wheel had been developed to supply hydromechanical power for mining operations and it was a simple matter to employ it to drive electric generators.

The most ambitious undertakings of that period were the Colgate plant, 2,700 kw in capacity, constructed in 1899 and transmitting power at 40,000 volts some 76 miles to Sacramento, and later in 1901 with a total installation of 9,240 kw transmitting power 142 miles at 60,000 volts to Oakland; and the Electra plant constructed in 1902, 10,000 kw, transmitting power, also at 60,000 volts, 154 miles to San Francisco.

In 1898, because of a shortage of water at Folsom, the idea of connecting two remote hydroelectric power supplies was conceived. In the following year, Sacramento, which had a steam plant, received power from the Colgate-Folsom interconnected power system. This proved later to be an occurrence of tremendous importance for such a tying together of hydroelectric plants and a steam plant to supply light to cities and to serve industry and agriculture with power established the principles:

1. That advantage could be taken of the diversity which exists in stream flow at different hydroelectric plants.

2. That a steam reserve furnished the desired continuity in hydroelectric service, and

3. That pooling of a regional demand, which varied daily, seasonally, geographically, and with character of energy usage, resulted in economy, owing to the greater number of hours which a given plant capacity could be effectively operated.

The interconnection of steam and hydro plants at Sacramento was followed in 1902 by the interconnection at Oakland of the Colgate and Electra hydro plants with each other and with the steam plants of the Bay region. Interconnection on a large scale had become a reality and the first or pioneer phase of development was completed.

Second Phase of Development (1902–31)

The second phase of development began shortly after the turn of the century. It was natural that the many separate companies should become consolidated in order to realize all of the advantages of co-ordinated operation and corporate simplicity. State regulation of the electric utilities was inaugurated in 1911 under the California Railroad Commission which has very broad regulatory powers, including jurisdiction over capitalization, consolidation, mergers, valuation, accounting practice, rates, service standards, complaints, and the issuance of certificates of public convenience and necessity. Competitive situations which produced wasteful duplication of facilities and destructive rate wars, gradually became replaced by a situation in which a few large, thoroughly integrated systems served the California power market at rates which continually declined as more of the benefits inherent in co-ordinated operation were realized.

It may be well at this point to review briefly the economic principles involved in a mingled hydro and steam power supply. Going back somewhat to first principles, the cost of power delivered at load centers, whether in California or elsewhere, depends upon the capital cost of generating plants, including transmission lines, and the resulting annual cost. The capital cost of steam plants at load centers with relatively short transmission, in general, is less than that of hydro plants with long transmission, which occasions lower fixed charges for steam plants. Giving consideration to the cost of fuel and the relatively high running expense, however, the cost of steam-generated energy, for 100 per cent load factor, tends to exceed the cost of hydro-generated energy. On the other hand, for low load factors, on account of the greater amount of hydro capital which is unproductively employed, and because of the small quantity of fuel required to generate the relatively small number of kilowatt-hours which obtain with low load factors, the cost of hydro-generated energy tends to exceed the cost of steam-generated energy. A low load factor and cheap fuel, then, suggest steam-plant development, whereas a high load factor and expensive fuel make hydro development attractive. In either case, the load factor has a determining effect on the cost of power whether it be supplied by steam plants, by hydro plants, or by a combination of both. It follows then, with a system load factor, usually of the order of 45 per cent (municipal loads) to 60 per cent (regional loads), if the load be divided into two parts, and the bottom or high-load-factor portion placed on hydro and the top or low-load-factor portion placed on steam, that a composite economy in power production will result. This, of course, assumes that the capital cost of hydro is not so low as to preclude the use of any steam, and that fuel is not so cheap as to preclude the use of any hydro.

Practically all water-power plants in California are subject to the disadvantage which attaches to the variability seasonally and annually of precipitation and corresponding runoff. Complete co-ordination of steam and hydro supplies is obtained when no hydro energy is wasted in the spring of a wet year and all steam capacity, with the exception of a reserve against accidents, is used at maximum capacity factor in the summer of a dry year. With conditions approaching this optimum, hydro will operate at high capacity factor in wet periods while steam will comb off low-load-factor peak and in dry periods hydro will take the low-load-factor peak leaving high-load-factor operation for steam. In any operating system there are a great many other complexities which modify and tend to prevent the accomplishment of maximum benefits. For example, steam plants in metropolitan areas and those supplying process steam to industries must carry some base load at all times, some hydro plants, due to lack of storage facilities, must operate as "run of stream" plants and not only have reduced capacity in a dry period but must operate at or near a constant rate, and owing to mandatory requirements for irrigation some hydro plants with storage facilities have restrictions upon their operation so cannot be operated at low load factor.

The operating agencies, as they became more familiar with power-supply economies, to the extent that they could exercise control endeavored to maintain an economic ratio between the capacity installed in hydro and in steam facilities. In the early part of this period the efficiency of steam plants was low, requiring about 40,000 Btu of heat to generate one kilowatt-hour so steam plants were installed primarily for standby. In the first decade the capacity installed in hydro facilities was some 263,000 kw compared to 93,000 kw of steam, that is, only 26 per cent of the total was steam-electric capacity.

In the second decade, the steam turbine replaced the older reciprocating engines, fuel was cheaper, and efficiency of generators had been increased until the heat required was reduced to 25,000 Btu per kilowatt-hour. In this decade the amount of hydro capacity installed was about 375,000 kva and the steam 250,000 kva, steam being 40 per cent of the total capacity installed in that period. Between 1920 and the end of this phase of development in 1931, a total of 1,185,000 kva of hydro and 848,000 kva of steam-electric capacity was installed and for this period the ratio of steam to the total was about 42 per cent. By 1931, the efficiency of steam plants had further increased so less than 12,000 Btu of heat was required to generate a unit of energy and if normal growth had continued, the ratio of steam to hydro would have been further increased, probably to a point where a kilowatt of steam would match each kilowatt of hydro installed.

In the beginning California had a number of separate markets, the principal ones being the mining towns near the hydroelectric plants, the industrial centers in the valleys, and the metropolitan centers along the sea coast. Northern California has always been favored with an abundance of hydro supplies so many plants were constructed and the transmission lines, 60,000 volts at that time, crossing the valleys between the hydro plants and the metropolitan areas were tapped en route with economy so the smaller agricultural communities also could be served. The market in the northern part of the state grew rapidly and by 1930 it, including 60 per cent of the farms in the territory, was well served with electricity. The population in northern California increased from 1,174,000 in 1900 to 2,740,000 in 1930, a substantial growth, but the use of electricity increased amazingly, namely, from an estimated 100,000,000 kilowatt-hours to approximately 4,880,000,000 kilowatt-hours in the same period.

At the beginning of the 20th century the market in the southern part of the state was about equal to that of the northern market, but in the first 15 years it did not grow as rapidly. Close-in hydro supplies were very limited and since steam-generated power then was very costly, it became necessary to develop the more remote sources in the southern end of the San Joaquin Valley and transmit the power to the area south of the Tehachapi. Beginning in 1915, the population of southern California began to increase at a phenomenal rate and by 1930 the population of the ten southern counties had reached 2,940,000 which was $9^{1}/_{2}$ times the population of 311,000 in 1900. The use of electricity increased from an estimated 100,000,000 kilowatt-hours in 1900 to approximately 4,300,000,000 kilowatt-hours in 1930. The total period growth, while also very large, was somewhat less than that in the north, but toward the latter part of the period, it gave every indication that the two markets soon would be substantially equal in magnitude.

The market in the southern part of the San Joaquin valley developed separately and was served by hydroelectric plants in that area. The expansion of the southern companies into the San Joaquin valley in search of hydro supplies ultimately caused about one-third of this market to be attached to southern California. The remainder of this market by reason of rapid growth which utilized most of the available hydro supplies, finally was served by the generating plants located in the north.

At the end of 1931, the southern market was served at two different frequencies by a number of agencies. Fifty-cycle current predominated with the principal distributors and 60-cycles with the others, and because of this, complete large-capacity interconnection of facilities has not been accomplished. The installed capacity serving the southern market at the end of this period aggregated 1,420,000 kva of which 684,000 kva was in hydroelectric and 737,000 kva in steam-electric facilities. The dry-year load capability of the total installation with due allowance for reserve capacity was to the order of 900,000 kw and approximately 5,000,000,000 kilowatt-hours.

The northern market was served by 1,553,000 kva of installed capacity of which 1,139,000 was in hydroelectric and 414,000 in steam-electric facilities. The frequency in this area is 60 cycles and all systems are interconnected. The dry-year load capability of these facilities, with allowance for reserves, was about 1,000,000 kw and 5,500,000,000 kilowatt-hours.

By 1930, southern California agencies had brought in substantially all of the potential hydro supplies available to that area, and were compelled to meet load growth by installing steam-electric plants. Consideration was given to the development of favorable medium-sized power sites on Colorado River but the adoption of the Boulder Canyon project by the Federal Government precluded development by private enterprise. At the end of this phase of development, southern California had only one close-in power resource of any magnitude, that is, steam-electric power generated in plants near tidewater where circulating water and fuel are available in ample quantities.

The situation in northern California was quite different, because there is a relatively large amount of potential hydro power, a substantial amount of which can be developed and transmitted to load centers at costs which are competitive with steam-electric power. In the late 20s the operating utilities in northern California had definite plans for hydroelectric development on Pit, Feather, Bear, Mokelumne, and Kings Rivers. These plans contemplated construction on all of these rivers during the decade 1930–1940, but this situation changed owing to the depression and to the interest of the State of California in a water-supply project for the Sacramento and San Joaquin Valleys, with incidental generation of a large block of hydroelectric power.

Attention should be directed to the fact that up to this time the use of electricity in California had continually increased, that is, the use in one year always had been greater than in the preceding year. Following 1931, however, the great depression produced a sharp reduction in power demand, a situation new to the central-station industry in this state, and one which soon caused utility companies to become concerned about the future.

The Third Phase—Inauguration of Large Federal Multipurpose Projects

It may be said that the Boulder Dam project marked the entrance of the Federal Government into the realm of power production on a large scale. This project, justifiable through necessity for flood control and planned, as to power, with the cooperation of public and private distribution agencies and with due regard to the requirements of the region in economic proximity to it, is sound economically and socially. Before the advent of the Boulder project, except as Federal authorization was necessary for the use of public lands for water-power development, the Government was not concerned, save in those cases of land reclamation which involved the generation of small amounts of power incidental to irrigation operations. The intrusion of the depression, and during it, the changes made in Federal administration, brought a further and drastic change in the relation of Government to power development, in which generation facilities were provided in disregard of the economic principles governing power development.

Following the further advance of the Federal Government into the field of hydroelectric production and transmission, there has been a trend away from the orderly development of power to meet growth, and economic laws and regulatory practices which have heretofore prevailed are ignored. With Government as a power producer the matter of answering public convenience and necessity, a requirement of regulation with the private utilities, has been disregarded and certain elements of cost are made to disappear in power economics. With tax exemption generally in Government projects, together with the allocation to navigation, flood control, and national defense, of a large part of the capital cost, the Government can set low power rates. While it is not the intention to condemn the entrance of the Government into the power business, nor to discuss at length the sociological significance of such a process, it will have a marked influence on values; but just what the ultimate economic and social effect will be is difficult to foretell.

1. Boulder Canyon Project and the Southern California Power Market

As mentioned before, the first of the large multipurpose reservoirs of the Federal Government to be constructed was on the Colorado River at Black Canyon. It was conceived principally because of the early necessity for controlling floods and the movement of silt in the Colorado River which constantly menaced the rich Imperial Valley and which, because that valley is below sea level, ultimately would have destroyed it. It was also capable of providing an adequate irrigation supply for large areas in Arizona and Nevada and for the Imperial and Coachella Valleys of California and a water supply for the coastal plain of southern California, which would permit that section of the state to develop for years to come. Without this water supply, the growth of southern California soon would be restricted.

The project had been studied by engineers for many years and was thoroughly investigated after the first legislation which authorized the Colorado River Compact between the seven interested states (Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming) was passed by Congress in 1921. The Boulder Canyon Project Act was the final outgrowth of all of these investigations and received executive approval in December 1928, subject, however, to subsequent ratification of at least six of the seven interested states. This approval of the six states was soon had and on June 25, 1929, eight years after the first legislation, the Boulder Canyon Act became effective.

The act provided for the construction of a dam at Black Canyon or Boulder Canyon and the construction of an all-American canal connecting the Imperial and Coachella Valleys with the Colorado River and authorized an expenditure for these works of $165,000,000. The act stipulated that construction would not begin at the dam until contracts had been negotiated which would secure revenue sufficient to insure payment of all expenses of operation and maintenance and the repayment within 50 years of the capital cost with interest. Construction of the all-American canal was contingent on negotiating contracts which would secure revenue sufficient to meet the cost of operation and maintenance and to repay the cost of construction in 40 equal annual installments without interest. It is estimated that the power contracts as finally negotiated will produce in the 50-year contract period a total revenue sufficient to pay off all of the costs of the dam including amortization of capital at four per cent interest and to provide a surplus of $129,000,000 for the use of the states in the Colorado River basin. Consideration now is being given to reducing the payment for falling water at the dam so the revenue in the 50-year period will retire all of the cost except $25,000,000 at $3^{1}/_{2}$ per cent interest and will accumulate a surplus of $55,000,000 for the basin states. It is stated that this plan if adopted will reduce the payment for falling water from 1.63 mils to approximately 1 mil per kilowatt-hour.

The construction in Black Canyon of the Hoover Dam and the allocation of the waters of the Colorado made it possible for the communities around Los Angeles to organize a water district for the purpose of bringing Colorado River water to them. The Metropolitan Water District was thus created and in due course, at a cost of $220,000,000 constructed a diversion dam on Colorado River 150 miles below Black Canyon, together with conveyance facilities, that is, pumping plants, pipe lines, tunnels, canals, and regulating reservoirs to deliver the water 290 miles to the coastal area of southern California. The district contracted for 36 per cent of the firm power and has first call on all secondary energy, because with ultimate water-supply demands, it will require this power to pump 1,600 second-feet of water against a total lift of over 1,600 feet.

The firm power at the dam is about 500,000 kilowatts and the power plant is designed to accommodate a total installation of 1,315,000 kva. All of this capacity will not be employed in the southern California power market, because of allocation of power for pumping on the Colorado River Aqueduct of the Metropolitan Water District. The capacity which is likely to be installed to supply the southern market and the commitments of the several agencies are as shown in table I.

Table I

		Commitment (Millions of Kilowatt-Hours)	
	Installation Kva	Firm Power	Secondary Power
Municipalities of Los Angeles, Pasadena, Glendale, and Burbank	495,000	1,773	700
Southern California Edison Co.	165,000	917	
Southern Sierras Power Co.	40,000	114	
	700,000	2,804	700

The total firm and secondary power which these agencies have obligated themselves to take is 3,500,000,000 kilowatt-hours or over 80 per cent of the total load in southern California in 1930. The firm power alone is 2,800,000,000 kilowatt-hours, and because of its magnitude each contracting agency was permitted to assume its obligation progressively over a period of four years, and since the private agencies did not begin taking power until three years after the municipalities began, the total period allowed for absorbing all the firm power is seven years.

Steam-electric power was the only large resource available for southern California, so the price paid for Boulder power was determined by the cost of producing steam-electric power at the load center. As it works out the price paid for falling water at the dam, plus the cost of generating and transmitting the power to the load center, plus the cost of steam standby produces a cost at the load center which is equal to the cost of steam-electric power there.

The power demand in southern California fell off rapidly during the great depression and did not again equal the 1930 demand until 1935. It became unnecessary to construct any of the steam-electric plants which in 1930 were planned to meet the expected growth of load in the period before Colorado River power was made available. The agencies in southern California were obligated to pay for the power when it became available so during this period their hope was for a resumption of load growth so the power could be absorbed. Fortunately, the tide turned in 1934 and the demand for power again began to increase. In 1935 it became equal to the previous maximum demand of the year 1930 and continued to increase until the end of 1937. There was no substantial growth in 1938, but it appears that 1939 again will show an increase in demand.

Present facilities and Colorado River power now contracted for should be capable of meeting a total load of 8,500,000,000 kilowatt-hours. The load of 1938 was 5,450,000,000 kilowatt-hours so if an average annual growth of five per cent can be maintained and complete interconnection is had, the Colorado River power would be absorbed by 1947. (The power would be absorbed in 1943 with a ten per cent rate of growth.)

The southern California market appears to be supplied with ample capacity for some time to come. Any addition required from now on will of necessity have to be provided in steam plants, unless the section of Colorado River below the dam where some 300,000 kw is available subsequently is developed for power purposes.

2. Central Valley Project and the Northern California Power Market

In 1921 the legislature of the State of California, realizing that the future growth of California was dependent in large measure on an adequate water supply, made appropriation to provide for a comprehensive investigation of the water resources of the state. This engineering investigation took place over a nine-year period, was financed by successive appropriations by the legislature, and culminated in a report to the legislature of 1931 on a comprehensive plan for the development of the water resources of California. Certain selected units of this comprehensive plan were recommended for early construction in order to serve those areas where the water problems already had become serious and which therefore required immediate attention. The facilities selected for initial construction in southern California included the Colorado River aqueduct and conservation and flood control works on the Santa Ana River basin. The facilities proposed for northern and central California became known as the Central Valley Project and included the following features:

1. *Features to Employ Sacramento River Water.* Kennett reservoir, located on upper Sacramento River, to be constructed to provide for flood control of the Sacramento River and to supply water to the industrial area on the south side of Suisun Bay, to irrigators in the lower San Joaquin Valley, and to prevent the encroachment into the Sacramento and San Joaquin Rivers of salt water from San Francisco Bay in dry years, and Contra Costa County conduit to convey water to the industrial area south of Suisun Bay and the San Joaquin River pumping system to convey water up San Joaquin Valley for the use of irrigators in the lower part of the valley.
2. *Features to Employ San Joaquin River Water.* Friant reservoir, located on upper San Joaquin River, for the purpose of supplying water to areas in the upper San Joaquin Valley, and Madera Canal, San Joaquin-Kern Canal, and Magunden-Edison pumping system conveying Friant water to points of use.

The cost of the project including a power plant at Kennett was estimated in the 1931 report to be $156,000,000, and the annual cost with state financing was stated to be about $2,800,000 more than the revenue which could be secured from the sale of electricity and water, even after complete utilization was had. The report stated, however, that the flood control and navigation benefits which would be produced would be so substantial that financial participation could be expected from the Federal Government and that if other interests which would be substantially benefited by the project also were assessed, sufficient income might be derived to carry the burden not capable of being carried by revenues from the sale of water and electric energy.

In 1933, the National Industrial Recovery Act was passed by Congress and in the desire to make the Central Valley Project eligible to receive Federal assistance the state legislature passed the Central Valley Project Act of 1933. This legislation authorized the construction of the project and created the Water Project Authority of the State of California to carry out the provisions of the act. The Water Project Authority sought financial assistance from the Federal Government in order to construct the project (then estimated to cost $170,000,000) as a State undertaking but without success, so in 1935 the Central Valley Project finally became authorized as a Federal project under the direction of the Bureau of Reclamation and active construction on some of the units commenced in 1937. The size of many of the units has been modified by the Bureau of Reclamation and to this time no authentic figures have been released by the Bureau regarding the estimated cost of the project, the proposed regimen of the water, the power to be generated, or the revenue required to repay the Federal Government for the reimbursable costs of the projects. All of this was known in the case of the Boulder Canyon project. Moreover, long-time contracts for water and power were executed before actual work began. However, the Central Valley Project is being constructed under the revised Federal policy to expend money on projects which are not self-liquidating, but which nevertheless contain elements of value and which during their construction furnish employment. All that is known now about the economics of the project is that there is an agreement between the Water Project Authority and the Bureau of Reclamation which contemplates that a further contract will be entered into between the same parties which will provide for the operation and maintenance of the project by the Water Project Authority upon its completion and for the assumption by it of the responsibility of reimbursing the United States for the funds advanced for the construction of the project and for securing appropriate contracts with local agencies and interests for the disposal of the water and power to be made available by the project in order to obtain revenues required for repayment.

The principal change which has been made which affects power produced on the project is an increase in the capacity of the proposed Shasta (formerly Kennett) reservoir and power plant. The production of hydroelectric power on this project is incidental to the primary water supply, salinity control, flood control, and navigation objectives and because of this the power does not possess characteristics which are as favorable as a project operated primarily to supply power. The installation provided for at Shasta is 375,000 kva of which 300,000 kva is to be installed at this time. According to reports of the Water Project Authority, the output of the plant will vary from 1,000,000,000 kilowatt-hours in a dry year to 2,000,000,000 kilowatt-hours in a wet year, the average being about 1,500,000,000 kilowatt-hours. There is some uncertainty as to how much of the installed capacity will be dependable. However, it is possible in a plan of operation which co-ordinates Shasta plant with all other generating facilities in the region to render substantially all of the 300,000 kilowatts now being installed dependable in that they can be made to add that amount of load capability to the regional power system without sacrificing the water-supply objectives of the project. For present purpose it is assumed, therefore, that the Shasta plant will supply a dependable increment of 300,000 kilowatts to the systems now serving the northern power market. It is estimated that the Shasta plant will become available in 1943.

The Central Valley Project was uncertain as to the magnitude of facilities and the date of completion until it was adopted as a Federal enterprise. Studies of the characteristics of Shasta power demonstrated that it would require the installation of a large amount of steam-electric power to effect complete absorption of the hydro energy. Furthermore, a market for the energy from Shasta could be prepared to effect its early utilization if steam-electric capacity or equivalent could be installed to meet the increase in demand which would develop prior to 1943, when Shasta becomes available. Such steam-electric plants, together with steam-electric plants already available could be operated at a high rate prior to the advent of Shasta and afterward the operation could be curtailed so Shasta plant could supply the energy which previously had been supplied by burning fuel.

The Water Project Authority in view of its contemplated responsibility for repayment to the United States of Federal funds advanced for construction of Central Valley Project, has concerned itself to see that no program of power development or power supply for northern California is carried out which may in any way hinder or delay the marketing of Shasta power when it becomes available. Pacific Gas and Electric Company, as principal distributor of power in the region, has modified its construction program to comply with this requirement of the Water Project Authority in so far as it could do so without causing the cost of power to be greater than it should be.

The predepression load of northern California reached its maximum in 1931, because that year was extremely dry and greater agricultural use of electricity was had than in 1930. The construction program of the lat 20s was not completed until 1931 when Pacific Gas and Electric Company brought in 71,000 kw of hydroelectric capacity on Mokelumne River and 130,000 kw of steam-electric capacity in San Francisco. This brought the dry year capability of the facilities available to the region, with sufficient capacity held in reserve to insure dependable service, to about 1,000,000 kw and 5,500,000,000 kilowatt-hours.

As mentioned before, the operating agencies in northern California had plans for extensive hydroelectric development during the decade 1930–40. The principal operating companies came under one management in 1930, and it became possible to co-ordinate the combined facilities in a manner which left some of the then-existing capacity available to meet load growth. Immediately thereafter the depression began and the load fell off, so none of the proposed hydroelectric projects were commenced. The Central Valley Project was authorized in 1933 and it became evident that prior to its completion it would be better to meet the growth of load by constructing steam-electric rather than hydroelectric plants—at least to the extent that such a program did not cause the cost of power to be higher than it would be were it to be supplied from other low-cost source.

The load in northern California fell off after 1931, remained at a low level through 1932 and 1933, and began to recover in 1934. In 1935 it became apparent that if the demand continued to increase it would be necessary to have additional capacity in 1937. This capacity was provided by means of a 75,000-kw interconnection with Southern California Edison Company and was followed in 1938 by additional storage facilities and the installation of 54,000 kw of steam-electric capacity in Oakland. Construction of 50,000-kw dual-purpose steam-electric plants at each of the oil refineries at Avon, Martinez, and Oleum is now [1939] under way and is scheduled for completion in 1940. This program will produce a dry year capability in 1940 of over 1,250,000 kw. If an average growth of five per cent is attained after 1937, this capacity should be capable of meeting the load of 1941 but new capacity will be required immediately thereafter. Pacific Gas and Electric Company proposes to bring in another plant of its Feather River project in 1942 because it is the most economic thing to do. Engineers of the Authority concede this, but believe that even though more costly, it is more in the public interest to continue with the construction of steam-electric plants so as to facilitate the absorption of Shasta energy.

All of the new facilities since 1931 are either steam-electric plants or purchased standby capacity (Southern California Edison Company), so a market thus is being prepared to permit the early absorption of the energy to be made available from Shasta plant. The amount of steam-electric capacity which will be available in 1940 in addition to preparing a ready market for the absorption of the energy from Shasta plant also is capable of providing dry-year support not only for all existing hydro plants, but for Shasta and the proposed Feather River plants of the Pacific Gas and Electric Company. It will not be necessary to install any more steam-electric capacity solely to support hydroelectric plants, private or public, until the load in northern California reaches a peak of over 1,750,000 kilowatts, 70 per cent above the load of 1938. However, it may be necessary to add some steam-electric reserve capacity to serve as standby in the southern end of the San Joaquin valley and as support for the close-in hydro supplies there, which in dry years become deficient and which are now being supported through long transmission lines from the generating plants located farther north.

With 1,250,000-kw capability in 1940, an orderly development thereafter predicated on a five per cent average rate of growth will require new capacity about as follows:

1942—68,000 kw on Feather River (or equivalent steam)
1943—300,000 kw at Shasta
1946—80,000 kw on Feather River
1947—38,000 kw on Feather River
75,000 kw of steam in San Joaquin valley

While this program is speculative as to date, from an economic standpoint it is the most desirable sequence of construction. The dry year capability at the end of this period, with some increase in reserves, will be 1,700,000 kw.

It is quite apparent that for some years after 1940, hydroelectric plants will predominate in northern California. There is about 600,000 kw of hydro capacity in addition to that mentioned which can be brought in competitive with steam-electric capacity. Owing to the fact that one-third of this does not require support the amount of steam required will be not to exceed one-half kilowatt for each kilowatt of hydro, thus the program following the hydro program outlined will include a combination of hydro and steam of 900,000 kw divided 600,000 kw to hydro and 300,000 kw to steam.

Power From Federal Multipurpose Projects

The large Federal multipurpose projects essentially are conservation projects constructed to attain one or more of several objectives, namely, flood control, salinity control, navigation improvement, and water supply for irrigation and domestic use. Generation of power on these projects, while important economically in that it can produce revenue to defray part or all of the cost of such projects, is incidental to the other objectives. The cost of the generating facilities themselves is relatively small, so the revenue from the sale of power generally can be made more than sufficient to carry the annual cost of the generating facilities leaving some surplus to meet a portion or all of the cost of the reservoir and other works.

While there is no uniform Federal policy in effect for establishing the cost of firm and secondary power on such projects, the tendency is to allocate to the several functions, portions of the total cost of facilities jointly used for the primary objectives and for power. Such allocations have been and must be somewhat arbitrary even though based on an estimate of the value of each benefit or as an alternative, on the cost of providing the benefit in some other manner. Allocations made to date on Tennessee Valley dams show 60 per cent of the cost of joint facilities to be charged to navigation and flood control and 40 per cent to power. The allocation at Bonneville is 67$^1/_2$ per cent to navigation and 32$^1/_2$ per cent to power.

Up to this time, power has been offered to customers as firm power (continuously available) and secondary power (available only part of the time). The prices set for Bonneville power appear to be somewhat less than the cost of producing power by steam or by other hydro plants, but the price set for Colorado River power will produce a cost at the load center which is substantially equal to the cost of generation in steam-electric plants. Furthermore, the contracts in this case provide for periodic revision of the rates, either upward or downward based on competitive conditions at load centers at the time of revision, so apparently it always was intended that firm Colorado River power at the switchboard should be sold so its cost at the load center just meets the cost of alternate firm power at the same place.

The foregoing method of selling power can produce substantial revenue for Federal multipurpose projects where a very large proportion of the available power is firm. The power to be generated at the Shasta plant of the Central Valley Project, owing to the many water-supply objectives, will not be nearly so firm as the power of Boulder Canyon project or Bonneville. It was estimated that there were nearly 500,000 kw of firm power at Boulder Canyon. From published articles it appears that at Bonneville there is firm power without storage on the upper Columbia River of approximately 200,000 kw and with storage this can be brought to about 500,000 kw. Contrasted to these figures various reports indicate that 30,000 to 75,000 kw of firm power, or 18 per cent to 43 per cent of the average output, may be available at the Shasta plant.

It is obvious that if the sale price is based on firm and secondary power as ordinarily defined, the power revenue of the Central Valley project would not compare favorably with revenue of the adjacent Federal multipurpose projects where the bulk of the power is firm, so the burden of cost of the project will weigh heavily on its water users if it is to be truly self-liquidating, or on the taxpayers of the nation if it is not self-liquidating. However, this situation can be greatly improved if the project is co-ordinated with the existing regional system to create the greatest use of the installed capacity and the maximum market for its energy.

Owing to the diversity of the power available from other plants in the region and to the variation of the demand throughout the year, it is possible so to co-ordinate the Shasta plant with the other generating facilities that most and possibly all of the capacity now being installed can be considered as supplying a dependable increment of capacity to the regional system. This being so, the annual value of that dependable increment of capacity should be the same as the cost of supplying an equal amount of capacity (but no energy) from the most economic alternate source. The annual value of the energy which can be employed would be the same as the cost of the fuel which would be required if the energy were generated in a steam-electric plant. This suggests that Shasta power in the interest of obtaining maximum revenue should not be sold as firm and secondary power as ordinarily defined, but instead should be sold on a two-part rate which employs one unit for dependable capacity and another unit for energy.

It should be recalled that most of the Federal multipurpose projects were inaugurated at the bottom of the depression as a means of stimulating economic recovery through the expenditure of Federal funds. These projects, almost without exception, are not truly self-liquidating, so it is necessary for the Federal Government to contribute to their cost the difference between the total cost and the amount reimbursable by the anticipated revenue from the project.

It is useless at this stage to discuss the merits and justification of this policy because that is water over the dam. The projects were started and one by one they are becoming realities, introducing their products to markets which are not entirely prepared to receive them.

It is in the public interest that these products be utilized as rapidly as possible. Consequently the full co-operation of all of the agencies which can contribute to this end, that is Federal, State, and local governments on the one hand, and distributors of power on the other hand, should be had. Existing distributing agencies should view the situation rationally and should be willing to take the power from the projects, assign all growth of load, that is, requirements for additional capacity—and operate their systems in the interests of creating maximum use of and also maximum value for this power to the extent that this can be done without financial loss.

Such a policy will permit the new generating facilities to be co-ordinated with all of those existing in proximity thereto so as to serve the regional power market and because this co-ordination enhances both the use and value of such power, it will produce maximum revenue in the shortest period of time, thus contributing to the economy of a given project by either reducing the cost of water, if water supply is an objective, or the amount of Federal contribution required to secure other objectives such as flood control, navigation, and others of peculiar local significance. This policy on the part of the power distributing agencies can be adopted without detriment to the consumers because they will pay the same for power as though the agencies had developed their own resources.

Conclusion

What has been presented is a brief review of the development of the production of mingled hydro and steam power in California, an outline of the economic advantages of co-ordinating the operation of a number of hydroelectric and steam-electric plants to supply a regional load, and a showing of the power demand in California with its segregation historically into a northern and a southern market. The two great Federal multipurpose projects, Boulder Canyon project in the south and Central Valley project in the north, profoundly affect their respective markets prior to, during, and immediately following the absorption of the capacity they make available. The agencies in southern California were allowed from six to nine years after signing their contracts in which to prepare to receive Colorado River power, consequently, notwithstanding the intervening depression and consequent lack of growth they are absorbing it in an orderly manner. The picture in northern California is somewhat obscured, but because the facilities which have been provided since the project became certain are steam-electric or standby, a favorable market is being prepared to receive Central Valley power, so with the co-operation of all interested parties, its absorption should present no serious problem by the time it becomes available.

As to the future, Southern California agencies, except for a limited hydro supply on Colorado River below Hoover Dam, generally will have to construct steam-electric plants to provide the capacity to meet growth of load. Northern California is more fortunate in that there are a number of hydroelectric projects which can be developed and which in combination with steam-electric plants will produce mingled power agreeable to the load on a competitive basis.

With orderly power development resumed after absorption of Central Valley power an extensive program of hydroelectric construction is a reasonable expectation, particularly so because of the prevailing low money cost which condition is likely to continue if the easy-money policy of the Government can be maintained. The only thing that would interfere with such a program is a discovery of unlimited supplies of fuel in close proximity to the market, which might be available at a price so low as to more than offset the advantage of low-cost money which is essential to hydro development.

Discussion

For discussion, see page 1077.

Fractional-Slot and Dead-Coil Windings

MICHEL G. MALTI
MEMBER AIEE

FRITZ HERZOG
NONMEMBER AIEE

1. Introduction

THE expression "fractional-slot windings" is commonly applied to machines where the number of slots is not an integer multiple of the product of the number of poles and phases. Dead-coil windings (D.W.) refer to windings where some of the slots contain wedges instead of coil sides. We shall use the term (F.W.) in this paper to comprise all windings which are not (D.W.). The term (F.W.) therefore comprises both whole-slot as well as fractional-slot windings which contain no dead coils.

The advantages of fractional-slot and dead-coil windings have been long recognized by designers. The following are some of the outstanding advantages:

(*a*). A great increase in the number of possible combinations of slots, poles, and phases and hence a consequent saving in the number and total cost of dies required by a manufacturing concern.

(*b*). A reduction in the magnetic locking and hence a decrease in the magnetic losses and a more smoothly operating machine.

The subject has been discussed by several writers. Tingley[1] seems to be the first to have written about fractional-slot windings. He devised a means of laying out windings by what he calls the L.C.M. (lowest common multiple) method. While his work is summarized in the form of tables, the theory underlying the preparation of these tables is not fully developed. Hence a person using Tingley's method for cases where it is not applicable, would obtain incorrect results and find himself at a loss to explain his error. Thus for an *m*-phase machine (*m* even and >2) Tingley's method does not apply. Moreover, Tingley's tables are incomplete in that they exclude some possible combinations of slots, poles, and phases. Again the tables are worked out for two- and three-phase machines only and do not cover six and twelve phases which are commonly used in rotary converters. Finally, Tingley restricts his treatment to the case where the number of coils is equal to the number of slots (double-layer winding). Riker and Dudley,[2] Seike,[3] and Kauders[4] following Tingley's footsteps elaborated on his tables but not on his method or theory. Sequenz[5] seems to have been the first to develop a theory of fractional-slot windings. Unfortunately, however, his work is a combination of rules of procedure and theoretical analysis. While he generalizes Tingley's treatment to *m*-phases, he excludes some possible combinations of slots, poles, and phases. Neither does Sequenz give a general relation for the possible combinations of slots, poles, and phases. Finally, none of these papers deals with dead-coil windings. They therefore fail to reveal the relation persisting between dead-coil and fractional-slot windings and eliminate several possible combinations of slots, poles, and phases.

The objects of this paper are:

(*a*). To develop the theory underlying *m*-phase fractional-slot and dead-coil windings.

(*b*). To give means of obtaining windings which satisfy the following conditions:

1. The electromotive forces of all the *m*-phases are equal in effective value.
2. The electromotive forces of successive phases are displaced from each other by $2\pi/m$ electrical radians.
3. The winding of each phase is as uniformly distributed over the armature as possible in order to give optimum electromotive force.

(*c*). To give expressions for the chording and distribution factors for fractional-slot and dead-coil windings.

(*d*). To obtain relations for possible combinations of slots, poles, and phases which give windings satisfying the conditions of paragraph *b*.

(*e*). To illustrate the theory developed and give rules of procedure for the designer.

2. nth Roots of Unity

(*a*). Definition

Engineers are familiar with at least two operators, the *j* operator which rotates a number by $\pi/2$ counterclockwise and the Fortescue *a* operator which rotates a vector by $2\pi/3$ counterclockwise. These operators are but special cases of an operator known as an *n*th root of unity. Thus if we have an equation $x^4-1=0$, then by writing $1=e^{j2\pi}$ we have $x^4=e^{j2\pi}$ or

---

Paper 39-134, recommended by the AIEE committee on electrical machinery, and presented at the AIEE combined summer and Pacific Coast convention, San Francisco, Calif., June 26–30, 1939. Manuscript submitted September 16, 1938; made available for preprinting May 18, 1939; released for final publication September 14, 1939.

Michel G. Malti is assistant professor of electrical engineering and Fritz Herzog is research associate, Cornell University, Ithaca, N. Y.

[1] For all numbered references, see list at end of paper.

$x = e^{j2\pi/4} = e^{j\pi/2} = j$. j is a fourth root of unity which rotates a vector by $2\pi/4$. Again if we have an equation $x^3 - 1 = 0$, then by writing $1 = e^{j2\pi}$ we have $x^3 - e^{j2\pi} = 0$ or $x = e^{j2\pi/3}$ which is Fortescue's *a* operator. It is a third root of unity and rotates a vector by $2\pi/3$ radians.

In general if we want to rotate a vector by $2\pi/n$ radians we multiply it by the operator $e^{j2\pi/n}$ which is an *n*th root of unity.

Now consider the equation

$$x^n - 1 = 0 \tag{1}$$

By writing $1 = e^{j2q\pi}$ where q is any integer we can find all the roots of (1) as follows:

$$x^n = 1 = e^{j2q\pi}$$

$$\mathbf{x}_q = e^{j2q\pi/n} = e^{j(q/n)2\pi} = e^{j\alpha q},$$

$$q = 0, 1, 2 \ldots (n-1) \tag{2}$$

The roots $\mathbf{x}_q$ in equation 2 are known as the *nth roots of unity* and are shown in figure 1 for $n = 6$. The *n*th roots of unity may be *primitive* or *nonprimitive*.

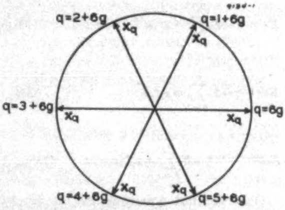

Figure 1. nth roots of unity for n = 6; g is any integer

If in equation 2 q is prime to n, then the *n*th root of unity is called a *primitive nth root* or a *root of order n*. If q is not prime to n then the root is *nonprimitive*. Hereafter the subscript q will be used to denote primitive *n*th roots of unity.

(*b*). PROPERTIES

The primitive *n*th roots of unity have the following properties which follow directly from equation 2:

1. Two integer powers of a primitive *n*th root of unity are equal if and only if the exponents differ by a multiple of *n* or:

If $k = r + gn$ then $\mathbf{x}_q^{\,k} = \mathbf{x}_q^{\,r}$ (3a)

and conversely

If $\mathbf{x}_q^{\,k} = \mathbf{x}_q^{\,r}$ then $k = r + gn$ (3b)

2. For every q in equation 2 which is prime to n, there exists an integer b such that

$$\mathbf{x}_q^{\,b} = e^{j2\pi/n} \tag{4a}$$

where

$$b = (1 + gn)/q \tag{4b}$$

In equation 4*b*, g must be properly chosen so that b is an integer. Thus if $n = 6$ and $q = 5$ then g can be 4, 9, 14, 19 ... etc., and b becomes 5, 11, 17, 23 ... respectively. Ordinarily the smallest possible b is selected because higher values of b simply mean an increase of the argument by a multiple of 2π.

3. All the *n*th roots of unity can be obtained from any primitive *n*th root of unity by raising that primitive root to a proper integer power or:

$$\mathbf{x}_q^{\,a} = \mathbf{x}_r \tag{5a}$$

where

$$a = br \tag{5b}$$

4. All positive-integer powers of a primitive *n*th root of unity between 0 and $(n-1)$ inclusive or between 1 and n inclusive are unequal or:

$\mathbf{x}_q^{\,k} \neq \mathbf{x}_q^{\,r}$ if $0 \leq k < r \leq n-1$ (6)

5. A primitive *n*th root of unity, when raised to integer powers k, will yield unity if and only if k is a multiple of n or:

$\mathbf{x}_q^{\,k} = 1$ if and only if $k = gn$ (7)

6. The smallest positive power to which a primitive *n*th root of unity may be raised to give 1 is n or:

$\mathbf{x}_q^{\,n} = 1$ and $\mathbf{x}_q^{\,n'} \neq 1$ if $1 \leq n' < n$ (8)

7. If $\mathbf{x}_r$ is an *n*th root of unity (primitive or not) then:

(*a*). $-\mathbf{x}_r$ is also an *n*th root of unity when n is even

(*b*). $-\mathbf{x}_r$ is not an *n*th root of unity when n is odd

8. If $\mathbf{x}_q$ is a primitive *n*th root of unity and if n is odd then the numbers $\pm\mathbf{x}_q^{\,kb}$, $k = 0, 1, 2, \ldots (n-1)$ represent all the $(2n)$th roots of unity.

3. The Phase Voltages of Fractional-Slot and Dead-Coil Windings

Let it be required to design a *c*-circuit winding for a $2p$-pole, m-phase, s-slot machine such that when the coils belonging to each phase or each circuit of each phase are equal and are connected in series we obtain a set of m-phase vector voltages which are equal in magnitude and equally displaced from each other by $2\pi/m$.

The following observations are pertinent:

(*a*). If we reduce the fraction s/p to its lowest terms we obtain:

$n/q = s/p$ in its lowest terms (9)

(*b*). From equation 9 we conclude that

$s/n = p/q$ is an integer (10)

(*c*). The angle α_q between slots (the slot pitch) is:

$$\alpha_q = p2\pi/s = (p/s)2\pi = (q/n)2\pi \tag{11}$$

Hence if we number the successive slots in a machine 1, 2, 3, ... s then:

1. Any two slots whose numbers differ by a multiple of n are 2π electrical radians apart and are thus in phase.

2. If n is even then any two slots whose numbers differ by an odd multiple of $n/2$ are π electrical radians apart and are mutually negative.

3. Any two slots whose numbers differ by $b = (1 + gn)/q$ (see equation 4*b*) are $2\pi/n$ electrical radians apart.

These statements can be readily verified by multiplying both sides of (11) by n, $n/2$, or b respectively.

(*d*). From observations *c* it follows that the number s_0' of slots, which are displaced by a multiple of π from any given slot is:

$s_0' = s/n$ if n is odd (12a)

$= 2s/n$ if n is even (12b)

(*e*). In an even-phased machine, any phase r is displaced from phase $r \pm m/2$ by π radians. This means that if m is even then, of two slots which are π apart, one is used for phase r and the other for phase $r \pm m/2$. In other words only half of the s_0' slots equation 12 can be used in any phase of an even-phased machine. We thus have the following relations for slots which are displaced from a given slot by a multiple of π in any given phase:

$s_0 = s/n$ if n and m are both even (13a)

$s_0 = 2s/n$ if n is even and m is odd (13b)

$s_0 = s/n$ if n and m are both odd (13c)

$s_0 = [\![s/2n]\!]$ if n is odd and m is even (13d)

The term $[\![s/2n]\!]$ is called the *bracket function* and is defined as follows:

$[\![x]\!] = x$ if x is an integer

$[\![x]\!] =$ the integer next smaller than x if x is not an integer

Thus $[\![4]\!] = 4$, $[\![3.6]\!] = 3$, $[\![-1.5]\!] = -2$

(*f*). From the foregoing observations and section 2 we conclude that the vector voltages $\mathbf{E}_0$ induced in the several coil sides have phase positions corresponding to the *n*th roots of unity. Moreover, since each coil may be connected in two ways, the vectors representing the induced voltages in the various coil sides may be positive or negative depending upon the mode of connection. Hence the balanced phase voltages $\mathbf{E}$, may be written as follows:

$$\mathbf{E} = \mathbf{E}_0 \sum_{k=1}^{h} \pm \mathbf{x}_q^{\,a_{0k}} \tag{14a$_0$}$$

$$\mathbf{E}e^{j2\pi/m} = \mathbf{E}_0 \sum_{k=1}^{h} \pm \mathbf{x}_q^{\,a_{1k}} \tag{14a$_1$}$$

$$\mathbf{E}e^{j2(2\pi/m)} = \mathbf{E}_0 \sum_{k=1}^{h} \pm \mathbf{x}_q^{\,a_{2k}} \tag{14a$_2$}$$

$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$

$$\mathbf{E}e^{j(m-1)2\pi/m} = \mathbf{E}_0 \sum_{k=1}^{h} \pm \mathbf{x}_q^{\,a_{(m-1)k}} \tag{14a$_{m-1}$}$$

where h is the number of used slots per phase and a_{jk} are, at present, unknown integers.

Equations 14 are the most general expressions for a balanced m-phase winding. The terms $\mathbf{x}_q^{\,a_{jk}}$ represent the individual voltages, generated in the various coil sides, which are connected in series to make up the winding of any one phase. Our object, henceforth, will be to evaluate the exponents $a_{\mu k}$ which enter into (14). Dividing equation $14a_1$ by equation $14a_0$ we obtain:

$$\epsilon^{j2\pi/m} = \sum_{k=1}^{h} \pm x_q^{a_{1k}} \Big/ \sum_{k=1}^{h} \pm x_q^{a_{0k}} \qquad (15)$$

It can be shown[7] that equation 15 holds only when one or the other of the following conditions is satisfied:

(*a*). n is divisible by m, or

(*b*). When n is odd, m is even and n is divisible by $m/2$.

This means that of all the cases mentioned in equation 13 only those cases which satisfy either condition *a* or condition *b* are possible. Moreover, in equations 13*a* to 13*c* condition *a* must be satisfied while in equation 13*d* condition *b* must be satisfied.

On the basis of the foregoing considerations, windings may be classified as outlined in table I.

Table I. Classification of Machine Windings

Type	n	m	Divisibility	a_0 (See Equations 13)
A	Even	Even	n is divisible by m.	s/n
B	Even	Odd	n is divisible by m.	$2s/n$
C	Odd	Odd	n is divisible by m.	s/n
D	Odd	Even	n is divisible by $m/2$.	$[\![s/2n]\!]$

Hereafter these types of windings will be referred to as types *A*, *B*, *C*, and *D* respectively. We shall find occasion to distinguish between two cases of *D*, namely, when $[\![s/2n]\!]=s/2n$ and when $[\![s/2n]\!]<(s/2n)$. The first type will be characterized as D_1 and the second as D_2. More specifically:

D_1 is a *D*-type winding where s is even
D_2 is a *D*-type winding where s is odd

4. Determination of h in Equations 14

The number of used slots per phase satisfies the following relations for fractional-slot and dead-coil windings respectively:

$$\text{For (F.W.) } h=s/m \qquad (16a)$$

$$\text{For (D.W.) } h=(s-Dm)/m=(s/m)-D \qquad (16b)$$

where D is the number of dead coils per phase.

5. Solution of Equations 14

We shall show how equations 14 may be solved for windings of types *A*, *B*, and *C* on the one hand and for windings of type *D* on the other hand.

(*a*). SOLUTION FOR TYPES A, B, AND C

To show how equations $14a_1$ to $14a_{m-1}$ are obtained from $14a_0$ if n is divisible by m we have the following identity:

$$\epsilon^{j(r/m)2\pi} = \epsilon^{j(2\pi/n)(rn/m)} \qquad (17a)$$

or

$$\epsilon^{j(r/m)2\pi} = x_q^{b(rn/m)} \qquad (17b)$$

Multiplying the right and left sides of (17*b*) respectively by the right and left sides of ($14a_0$) and using successively $r=0, 1, 2, \ldots (m-1)$ we have:

$$E=E_0\sum_{k=1}^{h} \pm x_q^{a_{0k}} \qquad (18a_0)$$

$$E\epsilon^{j2\pi/m}=E_0\sum_{k=1}^{h} \pm x_q^{(a_{0k}+bn/m)} \qquad (18a_1)$$

$$E\epsilon^{j2(2\pi/m)}=E_0\sum_{k=1}^{h} \pm x_q^{(a_{0k}+2bn/m)} \qquad (18a_2)$$

....

$$E\epsilon^{j(m-1)2\pi/m}=E_0\sum_{k=1}^{h} \pm x_q^{[a_{0k}+(m-1)bn/m]} \qquad (18a_{m-1})$$

It must be here emphasized that, once a sign plus or minus has been selected in ($18a_0$) for any one term of the sum that same sign should be used for the corresponding term in all succeeding equations of (18).

(*b*). SOLUTION FOR TYPE D

In this type, since m is even, equations 14 group themselves in pairs. Thus if $E\epsilon^{j\beta_y}$ is the voltage of phase y then $-E\epsilon^{j\beta_y}$ is the voltage of phase $(y \pm m/2)$. In particular the electromotive forces of phases 1 and $[(m/2)+1]$ are (see equations 14):

$$E\epsilon^{j0}=E \qquad (19a_0)$$

$$E\epsilon^{j(m/2)2\pi/m}=E\epsilon^{j\pi}=-E \qquad (19a_{m/2})$$

Since $m/2$ occurs rather frequently in this treatment we shall designate it by one letter μ thus:

$$m/2=\mu \qquad (20)$$

Substituting ($19a_0$) and ($19a_\mu$) in ($14a_0$) and ($14a_\mu$) we have:

$$E=E_0\sum_{k=1}^{h} \pm x_q^{a_{0k}} \qquad (21a)$$

$$-E=E_0\sum_{k=1}^{h} \pm x_q^{a_{\mu k}} \qquad (21b)$$

Now take equations 14 and divide them into two sets taking alternate equations to comprise any one set. Thus the *first set* would consist of equations $14a_0$, $14a_2$, $14a_4$, $\ldots$ $14a_{m-2}$ while the *second set* would comprise equations $14a_1$, $14a_3$, $\ldots$ $14a_\mu$ $\ldots$ $14a_{m-1}$.

The first set, with μ substituted for m, is identical in form with equations 14. Moreover since $\mu=m/2$ therefore μ is a divisor of n. Thus the *first set* is of the same form as equations 18 and may be written as follows:

$$E=E_0\sum_{k=1}^{h} \pm x_q^{a_{0k}} \qquad (22a_0)$$

$$E\epsilon^{j2\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{(a_{0k}+bn/\mu)} \qquad (22a_2$$

....

$$E\epsilon^{j(\mu-1)2\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{[a_{0k}+(\mu-1)bn/\mu]} \qquad (22a_{m-2})$$

As to the *second set* it consists of the following expressions:

$$E\epsilon^{j\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{a_{1k}} \qquad (23a_1)$$

$$E\epsilon^{j3\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{a_{3k}} \qquad (23a_3)$$

....

$$E\epsilon^{j\mu\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{a_{\mu k}} \qquad (23a_\mu)$$

....

$$E\epsilon^{j(m-1)\pi/\mu}=E_0\sum_{k=1}^{h} \pm x_q^{a_{(m-1)k}} \qquad (23a_{m-1})$$

Observe that equation $23a_\mu$ is simply the voltage $-E$. Now rearrange equations 23 starting with $23a_\mu$ and proceeding until you reach equation $23a_{m-1}$. Then take up equations $23a_1$, $23a_3$ $\ldots$ in succession. Equations 23 so rearranged will be the negative of the corresponding equations 23 and may be written as follows:

$$E\epsilon^{j\mu\pi/\mu}=-E=-E_0\sum_{k=1}^{h} \pm x_q^{a_{0k}} \qquad (24a_\mu)$$

$$E\epsilon^{j(\mu+2)\pi/\mu}=-E\epsilon^{j2\pi/\mu}$$

$$=-E_0\sum_{k=1}^{h} \pm x_q^{(a_{0k}+bn/\mu)} \qquad (24a_{\mu+2})$$

....

$$E\epsilon^{j(\mu-2)\pi/\mu}=-E\epsilon^{j(\mu-1)2\pi/\mu}$$

$$=-E_0\sum_{k=1}^{h} \pm x_q^{[a_{0k}+(\mu-1)bn/\mu]} \qquad (24a_{\mu-2})$$

It must be emphasized that, once a sign plus or minus has been selected in ($22a_0$) for any one term of the sum, that same sign should be used for the corresponding term in all the succeeding equations of (22) and (24).

Equations 22 and 24 comprise all the voltage equations of the m phases. Indeed equations $22a_0$ to $22a_{m-2}$ are respectively the voltage equations for odd-numbered phases, namely, 1, 3, 5, … $(m-1)$ and equations $24a_\mu$ to $24a_{\mu-2}$ are respectively the electromotive-force expressions for even-numbered phases, namely, $(1+m/2)$, $(3\pm m/2)$, $(5\pm m/2)$, …$[(m/2)-1]$ respectively.

Equations 18, 22, and 24 state that a balanced m-phase winding may be obtained in a variety of ways depending upon the values of $a_{01}, a_{02}, \ldots a_{0h}$ that are selected. Such a winding, however, may or may not give the optimum effective value E of the phase voltage, nor does it guarantee that s_0 of the coils which are π apart are in series per phase.

6. Optimum Voltage

In order to determine the exponents a_{0k} which give optimum E per phase we proceed in steps as follows:

(*a*). Determination of the Number of Times a Vector Is Repeated in (18a₀) and (22a₀)

Let an m-phase machine comprise c circuits per phase. Then the number of *used slots* per phase which are displaced from a given slot by π or 2π and which therefore yield equal vector voltages is:

$$s_{0u}=c[\![s_0/c]\!] \tag{25}$$

Now the number u of different vectors per phase is:

$$u=n/m \text{ for type } A \tag{26a}$$

$$=n/2m \text{ for type } B \tag{26b}$$

$$=n/m \text{ for type } C \tag{26c}$$

$$=2n/m=n/\mu \text{ for type } D \tag{26d}$$

But h is the total number of vectors per phase. Hence

$$h=us_{0u} \tag{27}$$

Equation 27 holds for both (F.W.) and (D.W.) and states that the terms h in (18), (22), (24) consist of u vectors each of which is repeated s_{0u} times.

In order to find the number of dead coils D per phase we simply substitute the value of h from equation 27 in (16b), solve for D and obtain

$$D=(s/m)-us_{0u} \tag{27a}$$

Making use of these facts, equations 18, 22, and 24 become respectively:

(*a*). *For Types A, B, and C*

$$E=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{a_{0k}} \tag{28a$_0$}$$

$$E\epsilon^{j2\pi/m}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+bn/m)} \tag{28a$_1$}$$

$$E\epsilon^{j2(2\pi/m)}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+2bn/m)} \tag{28a$_2$}$$

……

$$E\epsilon^{j(m-1)2\pi/m}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{[a_{0k}+(m-1)bn/m]} \tag{28a$_{m-1}$}$$

(*b*). *For Type D*

$$E=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{a_{0k}} \tag{29a$_0$}$$

$$E\epsilon^{j2\pi/\mu}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+bn/\mu)} \tag{29a$_2$}$$

$$E\epsilon^{j4\pi/\mu}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+2bn/\mu)} \tag{29a$_4$}$$

……

$$E\epsilon^{j(\mu-1)2\pi/\mu}=E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{[a_{0k}+(\mu-1)bn/\mu]} \tag{29a$_{m-2}$}$$

$$E\epsilon^{j\mu\pi/\mu}=-E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{a_{0k}} \tag{30a}$$

$$E\epsilon^{j(\mu+2)\pi/\mu}=-E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+bn/\mu)} \tag{30a$_{\mu+2}$}$$

$$E\epsilon^{j(\mu+4)\pi/\mu}=-E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{(a_{0k}+2bn/\mu)} \tag{30a$_{\mu+4}$}$$

……

$$E\epsilon^{j(\mu-2)\pi/\mu}=-E_0s_{0u}\sum_{k=1}^{u}\pm x_q^{[a_{0k}+(\mu-1)bn/\mu]} \tag{30a$_{\mu-2}$}$$

(*b*). Determination of a₀ₖ

In order to determine the a_{0k}'s in equations $28a_0$ and $29a_0$ which give optimum E we make use of theorems IIa and IIb which state that if we have equations of the form (28) or (29) then the values of a_{0k} which give an optimum E are given by (70) and (77) of the appendix respectively or:

(*a and b*). *For Types A and B*

$$E=E_0s_{0u}\sum_{k=1}^{u}x_q^{kb} \tag{31a$_0$}$$

$$E\epsilon^{j2\pi/m}=x_q^{bn/m}E_0s_{0u}\sum_{k=1}^{u}x_q^{kb} \tag{31a$_1$}$$

$$E\epsilon^{j4\pi/m}=x_q^{2bn/m}E_0s_{0u}\sum_{k=1}^{u}x_q^{kb} \tag{31a$_2$}$$

……

$$E\epsilon^{j(m-1)2\pi/m}=x_q^{(m-1)bn/m}E_0s_{0u}\sum_{k=1}^{u}x_q^{kb} \tag{31a$_{m-1}$}$$

(*c*). *For Type C*

$$E=E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{32a$_0$}$$

$$E\epsilon^{j2\pi/m}=x_q^{(bn/m)}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{32a$_1$}$$

$$E\epsilon^{j4\pi/m}=x_q^{(2bn/m)}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{32a$_2$}$$

……

$$E\epsilon^{j(m-1)2\pi/m}=x_q^{(m-1)bn/m}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{32a$_{m-1}$}$$

(*d*). *For Type D.* For phases 1, 3, 5, … $(m-1)$,

$$E=E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{33a$_0$}$$

$$E\epsilon^{j2\pi/\mu}=x_q^{bn/\mu}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{33a$_2$}$$

$$E\epsilon^{j4\pi/\mu}=x_q^{2bn/\mu}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{33a$_4$}$$

……

$$E\epsilon^{j(\mu-1)2\pi/\mu}=x_q^{(\mu-1)bn/\mu}E_0s_{0u}\left[\sum_{k=1}^{\frac12(u-1)}x_q^{kb}-\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{33a$_{m-2}$}$$

and for phases 2, 4, 6, … m,

$$E\epsilon^{j\mu\pi/\mu}=E_0s_{0u}\left[-\sum_{k=1}^{\frac12(u-1)}x_q^{kb}+\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{34a$_\mu$}$$

$$E\epsilon^{j(\mu+2)\pi/\mu}=x_q^{bn/\mu}E_0s_{0u}\left[-\sum_{k=1}^{\frac12(u-1)}x_q^{kb}+\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{34a$_{\mu+2}$}$$

$$E\epsilon^{j(\mu+4)\pi/\mu}=x_q^{2bn/\mu}E_0s_{0u}\left[-\sum_{k=1}^{\frac12(u-1)}x_q^{kb}+\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{34a$_{\mu+4}$}$$

……

$$E\epsilon^{j(\mu-2)\pi/\mu}=x_q^{(\mu-1)bn/\mu}E_0s_{0u}\left[-\sum_{k=1}^{\frac12(u-1)}x_q^{kb}+\sum_{k=\frac12(n+1)}^{\frac12(n+u)}x_q^{kb}\right] \tag{34a$_{\mu-2}$}$$

7. The Winding Layout

(*a*). Phase 1

Equations 31 to 34 are expressions for the electromotive forces per phase in an m-phase machine. Their utilization in the actual layout of the winding involves their interpretation in terms of slots on the machine. To do this we simply utilize the facts cited in observation *c* of section 3 and proceed as follows:

(*a*). Number the slots of the machine consecutively 1, 2, 3, . . . *s*.

(*b*). Lay out the winding for phase 1 only. This means that we interpret equations a_0 only.

(*c*). Since ($32a_0$) and ($33a_0$) are identical we need only consider equations $31a_0$ and $32a_0$ and in this way cover all the four types of windings.

(*d*). Write equations $31a_0$ and $32a_0$ as follows:

$$s_0\sum_{k=1}^{u} x_q^{kb} = \sum_{k=1}^{u} x_q^{kb} + \sum_{k=1}^{u} x_q^{kb} + \ldots + \sum_{k=1}^{u} x_q^{kb} \qquad (35a)$$

$$\begin{aligned} s_0\left[\sum_{k=1}^{\frac{1}{2}(u-1)} x_q^{kb} - \sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)} x_q^{kb}\right] = {} & \left[\sum_{k=1}^{\frac{1}{2}(u-1)} x_q^{kb} - \sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)} x_q^{kb}\right] + \\ & \left[\sum_{k=1}^{\frac{1}{2}(u-1)} x_q^{kb} - \sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)} x_q^{kb}\right] + \\ & \ldots\ldots\ldots\ldots\ldots\ldots\ldots + \\ & \left[\sum_{k=1}^{\frac{1}{2}(u-1)} x_q^{kb} - \sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)} x_q^{kb}\right] \end{aligned} \qquad (35b)$$

where (35*a*) holds for types *A* and *B* while (35*b*) is true for types *C* and *D*.

(*e*). All the sums to the right of (35*a*) or (35*b*) are identical and there exists s_0 of them.

(*f*). For further discussion of (35) we shall consider types *A*, *B*, and types *C*, *D*, separately.

1. TYPES A AND B

Let the electromotive forces represented by the first sum to the right of (35*a*) be produced by the coil sides which occupy slots *b*, 2*b*, . . . *ub*. Now observe that:

(*a*). All the sums to the right of (35*a*) are identical. Hence corresponding terms in all sums represent electrically identical slots.

(*b*). Slots which are electrically identical differ from each other by ($n/2$).

(*c*). From section 3, part *e*, we conclude that if *m* is even (type *A*) only half of the electrically identical slots (those which are *n* apart) are used for any one phase, the other half being used for the electrically opposite phase, while if *m* is odd (type *B*) all the electrically identical slots (those which are $^1/_2n$ apart) are used for one phase.

Table II. Slot Numbers in Which Top Coil Sides of Phase 1 Are Placed. This Table Is Applicable to Windings of Type A

	Slot Numbers for Phase 1					
k	$kb=c_1$	$kb+n=c_2$	$kb+2n=c_3$	$kb+3n=c_4$	****	$kb+(s_0-1)n=c_{s_0}$
1	b	$b+n$	$b+2n$	$b+3n$	****	$b+(s_0-1)n$
2	$2b$	$2b+n$	$2b+2n$	$2b+3n$	****	$2b+(s_0-1)n$
3	$3b$	$3b+n$	$3b+2n$	$3b+3n$	****	$3b+(s_0-1)n$
*	**	**	**	**	****	**
u	ub	$ub+n$	$ub+2n$	$ub+3n$	****	$ub+(s_0-1)n$

See notes table IV.

From these facts we conclude that the coil sides belonging to the first phase occupy slots:

$$(b+rn), (2b+rn) \ldots\ldots (ub+rn) \text{ in type } A \qquad (36a)$$

$$(b+rn/2), (2b+rn/2) \ldots\ldots (ub+rn/2) \text{ in type } B \qquad (36b)$$

$$\text{where } 0 \leq r \leq s_0-1,\ n \text{ is even} \qquad (36c)$$

It must be observed that if two coil sides are an odd multiple of π or ($n/2$) apart then they would be equivalent only if the connections are reversed. Hence alternate coil sides in (36*b*) must be reversed. This is shown by making the slot number negative in the following winding tables.

2. TYPES C AND D

Let the electromotive forces represented by the first sum to the right of (35*b*) be produced by the coil sides which occupy slots *b*, 2*b*, . . . $^1/_2(u-1)b$, $^1/_2(n+1)b$, $^1/_2(n+3)b$, . . . $^1/_2(n+u)b$. Now observe that:

(*a*). All the sums to the right of (35*b*) are identical. Hence corresponding terms in all sums represent electrically identical slots.

(*b*). Slots which are electrically identical differ from each other by *n*.

(*c*). From section 3, part *e*, we conclude that if *m* is odd (type *C*) all electrically identical slots (those which are *n* apart) are used for one phase. On the other hand, if *m* is even (type *D*) only half of the electrically identical slots are used for one phase while the other half are used for the electrically opposite phase (see equations 33 and 34).

(*d*). From remark (*c*) the (s/n) electrically identical slots in type *D* must be even in order that they may be divided equally between two mutually opposite phases. This means that *s* must be even or the winding must be of type D_1. If *s* is odd (type D_2) then one slot among those which are electrically identical must be dead. The remaining slots are even in number and may be therefore equally split between two mutually opposite phases. From these facts we conclude that:

1. The coil sides belonging to phase 1 in type *C* occupy slots number

$$\left.\begin{array}{l} (b+rn), (2b+rn), \ldots [^1/_2(u-1)b+rn], \\ \quad [^1/_2(n+1)b+rn], [^1/_2(n+3)b+rn], \ldots \\ \qquad [^1/_2(n+u)b+rn], 0 \leq r \leq (s_0-1) \end{array}\right\} \qquad (37)$$

2. The coil sides belonging to phase 1 and ($\mu+1$) in type *D* occupy slots number

$$\left.\begin{array}{l} (b+rn), (2b+rn), \ldots [^1/_2(u-1)b+rn], \\ \quad [^1/_2(n+1)b+rn], [^1/_2(n+3)b+rn], \ldots \\ \quad [^1/_2(n+u)b+rn], 0 \leq r \leq (s/n)-1 \end{array}\right\} \qquad (38)$$

It must be observed that the negative sign in (35*b*) simply means reversed connection of the coil side. Hence all coil sides occupying slots $[^1/_2(n+1)b+rn]$ to $[^1/_2(n+u)b+rn]$ in (37) must be connected in reverse. This is shown by marking the slot numbers negative in the accompanying tables.

These considerations enable us to construct tables II, III, IV, V, V*a*, and V*b* for slot numbers carrying coil sides belonging to phase 1.

(*b*). PHASES 2 TO m

Tables II to V give the winding layout for phase 1 or 1 and ($\mu+1$) only. In order to obtain the slot numbers corresponding to any other phase we make use of equations 31 and 32 which state that in types *A*, *B*, and *C* any phase is obtained from phase 1 by merely adding multiples of (bn/m) to the slot numbers of phase 1 and leaving coil connections unchanged. More particularly, in order to obtain the slot numbers for phase *y* add, to the numbers of phase 1, the number $(y-1)bn/m$. Thus for any column c_r the slot numbers for phase *y* in tables II, III, and IV are:

$$s_y = [c_r + (y-1)bn/m] \qquad (39)$$

For windings of type *D*, the slot numbers for any odd-numbered phase (see equations 33) are obtained by adding multiples of (bn/μ) to the slot numbers in phase 1, while the slot numbers for any even-numbered phase (see equations 34)

Table III. Slot Numbers in Which Top Coil Sides of Phase 1 Are Placed. This Table Is Applicable to Windings of Type B

	Slot Numbers for Phase 1						
k	$kb=c_1$	$(kb+n/2)=c_2$	$(kb+n)=c_3$	$(kb+3n/2)=c_4$	$(kb+2n)=c_5$	***	$kb+(s_0-1)n/2=c_{s_0}$

NOTE 1. If any number in the table is greater than s, then s or a multiple thereof must be subtracted from that number.

NOTE 2. The above slot numbers represent the slots in which the top side of a coil is placed. The bottom side of the same coil is placed in the slot number which meets the designer's requirement as to winding pitch.

NOTE 3. The negative sign following the slot number signifies that the coils in these slots are reverse connected.

NOTE 1. Notes 1 and 2, table IV, are applicable to table V.

NOTE 2. The number of columns in table V may be even or odd. If even, then the winding is type D_1. If odd, the winding is of type D_2 and one slot in each row must be left dead, thus leaving an even number of used slots in each row. Just what slot is left dead is a matter which the designer may himself determine.

NOTE 3. Half of the used slots in each row of the above table belongs to phase 1 and the other half to phase $\mu+1$. Just how to divide the slots in each row between the two phases is again optional with the designer.

NOTE 4. In connecting coil sides for phase 1 use direct connection for slot numbers occurring in the upper half of the table and reverse connection for slot numbers occurring in the lower half of the table. Use contrary connections for phase $\mu+1$.

NOTE 5. Having thus selected the slots which go into phases 1 and ($\mu+1$) with their proper signs construct two separate tables, the first for phase 1 and the second for phase ($\mu+1$). For example assume that the last column of table V is occupied by dead coils in case s/n is odd and that alternate columns are used for phases 1 and $\mu+1$. We then have tables V*a* and V*b*.

Table Va. Slot Numbers in Which the Top Coil Sides of Phase 1 Are Placed

	Slots for Phase 1

$^1/_2(n+u)$	$^1/_2(n+u)b-$	$[^1/_2(n+u)b+2n]-$	$[^1/_2(n+u)b+4n]-$	******	$[^1/_2(n+u)b+2(s_0-1)n]-$

See note, table V*b*.

are obtained by adding (bn/μ) to the slot numbers of phase ($\mu+1$). In both cases the mode of connection is unchanged. Thus for any column c_r' or c_r'' in tables V*a* and V*b* the slot numbers for phases ($2y+1$) and ($2y+1\pm\mu$) are respectively

$$s_{2y+1}=[c_r'+ybn/\mu] \qquad (40a)$$

$$s_{2y+1\pm\mu}=[c_r''+y(bn/\mu)] \qquad (40b)$$

8. Winding Comprising c Circuits

If the winding is to comprise c circuits then we have the following general principles to consider:

1. All slot numbers occurring in any one row of tables II to IV and V*a* to V*b* are electrically identical.

2. In order that the c circuits shall be balanced it is essential that each circuit comprise the same number of electrically identical coil sides.

3. Hence in splitting the winding into various circuits it is necessary to include in each circuit the same number of coil sides from any one row (tables II–IV and V*a*, V*b*). More specifically let us assume that the winding is to comprise c circuits. Then each row will furnish $[\![s_0/c]\!]$ coil sides to each circuit. Hence the total number of coil sides required for all the winding (see equation 25) is:

$$s_{0u}=c[\![s_0/c]\!] \qquad (41)$$

Now it sometimes happens that s_0/c is not an integer. In this case the remaining slots of any one table are occupied by dead coils Thus let s_d be the number of dead coils in each row then

$$s_d=s_0-c[\![s_0/c]\!] \qquad (42)$$

4. From the foregoing consideration it is obvious that only machines of types *A*, *B*, *C*, and D_1 in which s_0/c is an integer yield (F.W.). All others give (D.W.).

Just how the distribution of dead coils is to be carried out or in which way the winding is to be divided into the various circuits is a matter which has to be left to the discretion of the designer. The only caution being that given in paragraph 3 above.

9. Chording Factor

Let k_{WN} be the chording (winding pitch) factor for the *N*th harmonic. We

Table Vb. Slot Numbers in Which the Top Coil Sides of Phase ($\mu+1$) Are Placed

NOTE: Tables V*a* and V*b* are to be understood as being simply one choice. Many other choices of splitting table V present themselves (see notes 2, 3, and 5, table V).

shall compute this factor for (F.W.) and (D.W.) windings.

Let ψ be the winding pitch and let E_{cN} be the effective voltage induced per coil due to the Nth harmonic. Let $E_{c'N}$ be the algebraic sum of the Nth harmonic electromotive forces induced in the two coil sides. Then by definition

$$k_{WN}=E_{cN}/E_{c'N} \tag{43}$$

But

$$E_{c'N}=2E_{0N} \tag{44}$$

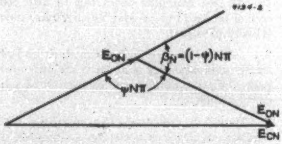

Figure 2. Vector voltages generated in two coil sides and their vector sum

As to E_{cN}, it may be computed by the use of figure 2 as follows:

$$E_{cN}^2=2E_{0N}^2-2E_{0N}^2\cos\psi N\pi \tag{45a}$$

$$=2E_{0N}^2(1-\cos\psi N\pi) \tag{45b}$$

But

$$1-\cos\theta=2\sin^2(\theta/2) \tag{46}$$

The substitution of (46) in (45) gives:

$$E_{cN}^2=4E_{0N}^2\sin^2(\psi N\pi/2) \tag{47a}$$

or

$$E_{cN}=2E_{0N}\,|\sin(\psi N\pi/2)| \tag{47b}$$

The substitution of (44) and (47*b*) in (43) gives

$$k_{WN}=|\sin(\psi N\pi/2)| \tag{48}$$

Equation 48 gives the chording factor for the Nth harmonic. This expression can be used effectively in eliminating any harmonic from the voltage equation. Thus in order to eliminate the Nth harmonic k_{WN} must be zero. This means

$$\psi N\pi/2=\sigma\pi \tag{49a}$$

or

$$\psi=2\sigma/N \tag{49b}$$

The Nth harmonic is eliminated by making the winding pitch $\psi=2\sigma/N$ where σ is such an integer that $2\sigma<N$. For example in order to eliminate the third or fifth harmonic make $\psi=2/3$ or $\psi=4/5$ respectively.

10. The Distribution (Slot) Factor

Let E_{aN} be the algebraic sum of the Nth harmonic electromotive forces generated in the coil sides of any one phase. Let E_{vN} be the magnitude of the vector sum of the same Nth harmonic electromotive forces. Then by definition:

$$k_{sN}=E_{vN}/E_{aN} \tag{50}$$

We shall develop the distribution factors for types *A* and *B* and types *C* and *D* separately.

(*a*). DISTRIBUTION FACTOR FOR TYPES A AND B

In equations 31 there are $(s_{0u}u)$ coil sides any one of which may be represented by the vector $E_{0N}x_e^{kbN}=E_{0N}\epsilon^{jkN2\pi/n}$ where k varies from 1 to u. Thus the sum of the moduli of these vectors is:

$$E_{aN}=(s_{0u}u)E_{0N} \tag{51}$$

The vector sum is:

$$E_{vN}=E_{0N}s_{0u}[\epsilon^{jN(2\pi/n)}+\epsilon^{j2N(2\pi/n)}+\epsilon^{j3N(2\pi/n)}+\ldots+\epsilon^{juN(2\pi/n)}] \tag{52a}$$

$$E_{vN}=E_{0N}s_{0u}[(\epsilon^{jN2\pi/n})+(\epsilon^{jN2\pi/n})^2+(\epsilon^{jN2\pi/n})^3+\ldots+(\epsilon^{jN2\pi/n})^u] \tag{52b}$$

Now observe that the terms within brackets in (52*b*) constitute a geometric series. Hence the expression for the sum of a geometric series may be used to represent the quantity within brackets and we have:

$$E_{vN}=E_{0N}s_{0u}[(1-\epsilon^{juN2\pi/n})/(1-\epsilon^{jN2\pi/n})]\times\epsilon^{jN2\pi/n} \tag{53}$$

Multiply the right and left sides of (53) respectively by their conjugates and obtain:

$$E_{vN}^2=E_{0N}^2s_{0u}^2[(1-\epsilon^{juN2\pi/n})\times(1-\epsilon^{-juN2\pi/n})]/[1-\epsilon^{jN2\pi/n}]\times[1-\epsilon^{-jN2\pi/n}] \tag{54a}$$

$$E_{vN}^2=E_{0N}^2s_{0u}^2[1-\epsilon^{-juN2\pi/n}-\epsilon^{juN2\pi/n}+1]/[1-\epsilon^{-jN2\pi/n}-\epsilon^{jN2\pi/n}+1] \tag{54b}$$

$$E_{vN}^2=E_{0N}^2s_{0u}^2[1-\cos(uN2\pi/n)]\div[1-\cos(N2\pi/n)] \tag{54c}$$

The use of relation (46) reduces equation 54*c* to the following expression:

$$E_{vN}^2=E_{0N}^2s_{0u}^2[2\sin^2(uN2\pi/n)]\div[2\sin^2(N2\pi/n)] \tag{55a}$$

or

$$E_{vN}=|E_{0N}s_{0u}\sin(uN2\pi/n)/\sin(N2\pi/n)| \tag{55b}$$

The substitution of (55) and (51) in (50) yields:

$$k_{sN}=\left|\frac{\sin(uN2\pi/n)}{u\sin(N2\pi/n)}\right| \tag{56}$$

which is the distribution factor for the Nth harmonic in windings of types *A* and *B*.

(*b*). DISTRIBUTION FACTOR FOR TYPES C AND D

In equations 32 and 33 there are $(s_{0u}u)$ coil sides any one of which may be represented by the vector $E_{0N}x_e^{kbN}=E_{0N}\times\epsilon^{jkN2\pi/n}$ where k varies from 1 to $^1/_2(u-1)$ and from $^1/_2(n+1)$ to $^1/_2(n+u)$. Thus the sum of the moduli of these vectors is:

$$E_{aN}=(s_{0u}u)E_{0N} \tag{57}$$

The vector sum is given by equation 78 of theorem II*b* of the appendix or:

$$E_{vN}=E_{0N}s_{0u}\sum_{r=1}^{u}(\epsilon^{jN2\pi/2n})^r \tag{58a}$$

$$=E_{0N}s_{0u}[\epsilon^{jN\pi/n}+(\epsilon^{jN\pi/n})^2+(\epsilon^{jN\pi/n})^3+\ldots+(\epsilon^{jN\pi/n})^u] \tag{58b}$$

since (58*b*) is a geometric series it may be written as follows:

$$E_{vN}=E_{0N}s_{0u}[(1-\epsilon^{juN\pi/n})/(1-\epsilon^{jN\pi/n})]\times\epsilon^{jN\pi/n} \tag{59}$$

Multiply the right and left sides of (59) by their conjugates and obtain:

$$E_{vN}^2=E_{0N}^2s_{0u}^2[1-\cos(uN\pi/n)]\div[1-\cos(N\pi/n)] \tag{60}$$

The use of relation (46) reduces equation 60 to the following expression:

$$E_{vN}=|E_{0N}s_{0u}\sin(uN\pi/n)/\sin(N\pi/n)| \tag{61}$$

The substitution of (61) and (57) in (50) yields

$$k_{sN}=\left|\frac{\sin(uN\pi/n)}{u\sin(N\pi/n)}\right| \tag{62}$$

which is the distribution factor for the Nth harmonic in windings of types *C* and *D*.

11. Possible Combinations of s, p, and m

In practical applications a designer is faced with the problem of ascertaining what combinations of slots, poles, and phases will give a balanced m-phase winding. More particularly the purchaser specifies the number of phases m, the frequency, and the speed of the machine. Thus m and p are specified and it is required to find the number of slots s which yield a balanced winding. We give below a method of determining s.

Referring to table I we observe that:

(*a*). In windings of types *A*, *B*, and *C*, n must be divisible by m.

(*b*). In windings of type *D*, n must be divisible by $m/2$. Moreover since n is odd, m must be the double of an odd integer.

(*c*). If m is odd then we have types *B* or *C*. In each case n must be divisible by m.

(*d*). If m is even then we have types A or D. Here we distinguish between the following two cases:

1. m is the double of an odd integer ($m=4k+2$). This may give types A or D and in either case n is divisible by $m/2$.
2. m is the double of an even integer ($m=4k$). This always leads to type A where n is divisible by m.

The above observations may be summarized in tabular form as table VI. Now let m_k be the different prime factors of m in cases 1 and 3 and of $m/2$ in case 2. Then:

$$m=\prod_r m_r^{a_r} \text{ in cases 1 and 3} \tag{63a}$$

$$m=2\prod_r m_r^{a_r} \text{ in case 2} \tag{63b}$$

$$\text{where } a_r>0 \text{ and } m_r\neq 1 \tag{63c}$$

From equations 63 and the conditions of divisibility of table VI we conclude that in all three cases n must be divisible by $\prod_r m_r^{a_r}$. But, by theorem III of the appendix, the only machines which can be wound are those having slots s such that:

$$s=HG \tag{64a}$$

$$\text{where } H=mp_1 \text{ in cases 1 and 3} \tag{64b}$$

$$=(m/2)p_1 \text{ in case 2} \tag{64c}$$

p_1 is defined by equation 83 of the appendix and G is any integer.

These considerations lead to the possible combinations of slots, poles, and phases of table VII.

Table VI. Relations Between n and m in the Various Types of Windings

Case	m	Possible Types of Winding	Divisibility Conditions
1	$2k+1$	B or C	n is divisible by m
2	$4k+2$	A or D	n is divisible by $m/2$
3	$4k$	A	n is divisible by m

94	1	3	4	5	7	8	9	11	12	13	15	16	20	24	28
96	1	9	64	5	7	128	27	11	576	13	45	256	320	1,152	448
98	1	3	4	5	343	8	9	11	12	13	15	16	20	24	1,372
100	1	3	8	125	7	16	9	11	24	13	375	32	1,000	48	56

NOTE 1. The number in each block is H in equation 64.

NOTE 2. Referring to theorem IV of the appendix and table XVII observe that if $m=4k+2$ and s is odd and if s and p are relatively prime then $s=n$ and $s_0=[\![s/2n]\!]=0$. Hence s should be so selected that the following relations are not simultaneously satisfied: (1) $m=4k+2$, (2) s is odd, and (3) s and p are relatively prime.

12. Possible Combinations of s, p, and m Which Yield c-Circuit (F.W.)

The slot combinations given in table VII hold for both D.W. and F.W. A matter of particular interest to the designer is when D.W. may be avoided. We shall concern ourselves here with the problem of possible combinations of s, p, and m, which yield a c-circuit (F.W.).

It must be emphasized at the outset that all windings of type D_2 are necessarily (D.W.). However windings of type A, B, C, and D_1 may be F.W. or D.W. depending on whether s_0/c is or is not an integer. In order to obtain F.W. the following conditions must be satisfied:

(*a*). The winding must be of type A, B, C, or D_1.

(*b*). s_0/c must be an integer.

It is the object of this article to answer the following question: What numbers s (obtained from table VII) yield F.W. for any given combination of m, p, and c?

This question is answered in theorem IV of the appendix. We here give the summary of the results in table VIII. In order to use the table proceed in steps as follows:

1. Determine whether m belongs to case 1, 2, or 3.
2. Ascertain whether $2p$ is divisible by c or p is divisible by c as the case may be.
3. Select s from table VII so that s is divisible by c or $2c$ as the case may be.

13. Illustrative Problems

We shall illustrate the foregoing theory by solving five problems which yield windings of types A, B, C, D_1, and D_2, respectively. Thus let it be required to lay out windings for the following machines:

Machine *a*—four-phase, 6- pole, 80 slots
Machine *b*—three-phase, 10-pole, 54 slots
Machine *c*—three-phase, 4-pole, 45 slots
Machine *d*—six-phase, 8-pole, 60 slots
Machine *e*—six-phase, 18-pole, 135 slots

The work will be tabulated in order to conserve space (tables IX, X, XI, XII, XIII, XVI, XV, and XVI).

Table VIII. Necessary and Sufficient Conditions for a c-Circuit F.W.

Case	m	s	Conditions to Be Satisfied
1	$2k+1$	Table VII	$2p$ is divisible by c and s is divisible by c
2	$4k+2$	Table VII	p is divisible by c and s is divisible by $2c$
3	$4k$	Table VII	p is divisible by c and s is divisible by c

Table IX. Constants Entering Into the Winding Formulas

Item Number	Symbol	Equation Number	Formula	a	b	c	d	e
				Value of Item for the Five Machines				
1	s	Given		80	54	45	60	135
2	p	Given		3	5	2	4	9

4	n q	(9)	$n/q = s/p$ in its lowest terms	80 3	54 5	45 2	15 1	15 1
5	Type	Table I		A	B	C	D_1	D_2
6	u	(26)	$u = n/m$ for types A, C $u = n/2m$ for type B $u = 2n/m$ for type D	20	9	15	5	5
7	s_0	Table I		1	2	1	2	4
8	b	(4)	$(1+gn)/q$	27	11	23	1	1
9	s/n			1	1	1	4	9

Table X. Winding Layout for Phases 1, 2, 3, and 4 of Machine a (See Table II and Equation 39)

Phase Number	Equation for Slot Numbers	k: 1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20
1	kb	27	54	1	28	55	2	29	56	3	30	57	4	31	58	5	32	59	6	33	60
2	$kb+bn/m$	7	34	61	8	35	62	9	36	63	10	37	64	11	38	65	12	39	66	13	40
3	$kb+2bn/m$	67	14	41	68	15	42	69	16	43	70	17	44	71	18	45	72	19	46	73	20
4	$kb+3bn/m$	47	74	21	48	75	22	49	76	23	50	77	24	51	78	25	52	79	26	53	80

NOTES:

1. Numbers in the above squares represent the slot numbers in which the top coil side of the various phases are placed.

2. The above winding may be used for a two-phase machine by reversing the terminals of phase 3 and connecting in series with phase 1 to form phase a and reversing the terminals of phase 4 and connecting in series with phase 2 to form phase b.

3. It must be here emphasized that our method of winding gives, for a two-phase machine, two equal and opposite phases. To obtain a two-phase machine in which the phases are in quadrature the machine should be first wound as if it were four phase and then the winding connected as explained in note 2 above.

4. Since $s_0 = 1$ and since, by equation 25, $s_{0u} = [\![s_0/c]\!]c = 0$ if $c > 1$ the winding cannot have more than one circuit.

Table XI. Winding Layout for Phases 1, 2, and 3 of Machine b (See Table III and Equation 39)

	Slot Numbers Phase 1		Slot Numbers Phase 2		Slot Numbers Phase 3	
k	$kb - c_1$	$kb + n - c_2$	$c_1 + bn/m$	$c_2 + bn/m$	$c_1 + 2bn/m$	$c_2 + 2bn/m$
1	11	38−	47	20−	29	2−
2	22	49−	4	31−	40	13−
3	33	6−	15	42−	51	24−
4	44	17−	26	53−	8	35−
5	1	28−	37	10−	19	46−
6	12	39−	48	21−	30	3−
7	23	50−	5	32−	41	14−
8	34	7−	16	43−	52	25−
9	45	18−	27	54−	9	36−

NOTE: Since $s_0 = 2$ and since, by equation 25, $s_{0u} = [\![s_0/c]\!]c = 0$ if $c > 2$ the above winding cannot have more than two circuits. For a two-circuit winding column 1 of each phase may be used for circuit number 1 and column 2 for circuit number 2.

14. Summary

We have developed a theory of fractional-slot (F.W.) and dead-coil (D.W.) windings and have shown the relation between the two classes. This theory might appear formidable to some designers. It can be, however, reduced to some very simple rules of thumb which are easily understood and applied by even the most naive individual. Indeed the process of laying out a winding according to our theory involves the simplest and most elementary processes of algebra and could be readily summarized in steps as follows.

(a). From the customer's specifications of a machine the designer knows

1. The number of phases m.
2. The number of poles $2p$.

(b). By consulting table VII he can readily tell the slot numbers that could be used to obtain a windable machine. Thus for a 12-pole, three- or six-phase machine the slot numbers must be multiples of 9. The designer can therefore use 9 or 18 or 27 or 36 or . . . $9k$ slots. The actual number of slots he selects depends upon such factors as the number of conductors he obtains from the voltage equation, the stock dies available, the number of circuits c, etc.

(c). In case the designer wishes to make his winding of more than one circuit it is advisable that he refer to table VIII. Here he can at once ascertain whether c circuits are at all possible with F.W. Thus, referring to table VIII, if $m = 2k+1$ and if $2p$ is

Table XII. Winding Layout for Phases 1, 2, and 3 of Machine c (See Table IV and Equation 39)

Phase Number	Equation for Slot Numbers	k: 1	2	3	4	5	6	7	23	24	25	26	27	28	29	30
1	kb	23	1	24	2	25	3	26	34−	12−	35−	13−	36−	14−	37−	15−
2	$kb+bn/m$	8	31	9	32	10	33	11	19−	42−	20−	43−	21−	44−	22−	45−
3	$kb+2bn/m$	38	16	39	17	40	18	41	4−	27−	5−	28−	6−	29−	7−	30−

NOTE. Since $s_0 = 1$ and since, by equation 25, $s_{0u} = [\![s_0/c]\!]c = 0$ if $c > 1$, the winding cannot have more than one circuit.

divisible by c then by selecting s divisible by c he can obtain F.W. otherwise he will have D.W.

(*d*). The designer how has m, p, and s. By using table IX he can:

1. Compute the constants, n, q, u, s_0, b, s/n which enter into the winding formulas of the machines.
2. Ascertain the type of winding he gets.

These computations involve nothing but the simple algebraic processes of multiplication, division, and reduction of a fraction to its lowest terms.

Table XIII. Slot Numbers for Phases 1 and 4 of Machine d (See Table V)

k	$kb=c_1$	$kb+n=c_2$	$kb+2n=c_3$	$kb+3n=c_4$
1	1	16	31	46
2	2	17	32	47
8	8	23	38	53
9	9	24	39	54
10	10	25	40	55

NOTE: In order to divide the slot numbers among the two phases we use the principle given in note 3 following table V. Thus one way of splitting table XIII is to take columns c_1 and c_2 for phase 1 and columns c_3 and c_4 for phase 4. With this mode of splitting we obtain the following table for the winding layout of machine *d*.

(*e*). Knowing the type of winding and the winding constants the designer now constructs a table following the patterns of tables II, III, IV, or V for windings of type *A*, *B*, *C*, or *D* respectively thereby obtaining the slot numbers for phase 1 or for phases 1 and $\mu+1$ as the case may be.

(*f*). In order to obtain the slot numbers for any of the remaining phases (say phase *y*) he uses equation 39 for types *A*, *B*, and *C* and equations 40 for type *D* as illustrated in tables X to XVI.

(*g*). In order to compute the chording factor for the *N*th harmonic use equation 48.

Table XIV. Winding Layout for Machine d (See Table XIII and Equations 40)

	Slot Number for the Various Phases											
	Phase 1		Phase 3		Phase 5		Phase 4		Phase 6		Phase 2	
k	c_1	c_2	c_1+bn/μ	c_2+bn/μ	c_1+2bn/μ	c_2+2bn/μ	c_3	c_4	c_3+bn/μ	c_4+bn/μ	c_3+2bn/μ	c_4+2bn/μ
1	1	16	6	21	11	26	31 −	46 −	36 −	51 −	41 −	56 −
2	2	17	7	22	12	27	32 −	47 −	37 −	52 −	42 −	57 −
8	8 −	23 −	13 −	28 −	18 −	33 −	38	53	43	58	48	3
9	9 −	24 −	14 −	29 −	19 −	34 −	39	54	44	59	49	4
10	10 −	25 −	15 −	30 −	20 −	35 −	40	55	45	60	50	5

NOTE 1. See note following table XI.

NOTE 2. See note 4 following table V which explains mode of connection.

Table XV. Slot Numbers for Phases 1 and 4 of Machine e (See Table V)

k	$kb=c_1$	$kb+n=c_2$	$kb+2n=c_3$	$kb+3n=c_4$	$kb+4n=c_5$	$kb+5n=c_6$	$kb+6n=c_7$	$kb+7n=c_8$	$kb+8n=c_9$
1	1	16	31	46	61	76	91	106	121
2	2	17	32	47	62	77	92	107	122
8	8	23	38	53	68	83	98	113	128
9	9	24	39	54	69	84	99	114	129
10	10	25	40	55	70	85	100	115	130

NOTE: In order to divide the slot numbers among the two phases we use the principle given in notes 2 and 3 following table V. Thus one way of splitting table XV is to take the slot numbers in the first four columns for phase 1, the slot numbers in the next four columns for phase 4, and make the slot numbers in the last column dead. With this mode of splitting we obtain table XVI for the winding layout of machine *e*.

Table XVI. Winding Layout for Machine e (See Table XV and Equations 40)

	Slot Numbers for the Various Phases											
	Phase 1				Phase 3				Phase 5			
k	c_1	c_2	c_3	c_4	c_1+bn/μ	c_2+bn/μ	c_3+bn/μ	c_4+bn/μ	c_1+2bn/μ	c_2+2bn/μ	c_3+2bn/μ	c_4+2bn/μ
1	1	16	31	46	6	21	36	51	11	26	41	56
2	2	17	32	47	7	22	37	52	12	27	42	57
8	8 −	23 −	38 −	53 −	13 −	28 −	43 −	58 −	18 −	33 −	48 −	63 −
9	9 −	24 −	39 −	54 −	14 −	29 −	44 −	59 −	19 −	34 −	49 −	64 −
10	10 −	25 −	40 −	55 −	15 −	30 −	45 −	60 −	20 −	35 −	50 −	65 −

	Phase 4				Phase 6				Phase 2			
	c_5	c_6	c_7	c_8	c_5+bn/μ	c_6+bn/μ	c_7+bn/μ	c_8+bn/μ	c_5+2bn/μ	c_6+2bn/μ	c_7+2bn/μ	c_8+2bn/μ
1	61 −	76 −	91 −	106 −	66 −	81 −	96 −	111 −	71 −	86 −	101 −	116 −
2	62 −	77 −	92 −	107 −	67 −	82 −	97 −	112 −	72 −	87 −	102 −	117 −
8	68	83	98	113	73	88	103	118	78	93	108	123
9	69	84	99	114	74	89	104	119	79	94	109	124
10	70	85	100	115	75	90	105	120	80	95	110	125

NOTE: Since $s_0=4$ and since by equation 25 $s_{0u}=[\![s_0/c]\!]c=0$ if $c>4$ the above winding cannot have more than four circuits. For a two-circuit winding use columns 1 and 2 of each phase for the first circuit and columns 3 and 4 for the second circuit. For a four-circuit winding use one column of each phase for each circuit. A three-circuit winding could be had by sacrificing one column in each phase and occupying the slots in that column by dead coils.

(*h*). In order to compute the slot (distribution) factor for the *N*th harmonic use (56) for types *A* and *B* and equation 62 for types *C* and *D*.

(*i*). *Caution:* It must be emphasized that our theory gives, in the case of two-phase machines, phases that are 180 degrees apart. In order to obtain a two-phase machine with a phase displacement of 90 degrees proceed as though the machine were four-phase then connect phases 1 and 3 in series to obtain phase *a* and 2 and 4 in series to obtain phase *b*. This is illustrated by machine *a*, table X.

(*j*). It should be further emphasized that (see equations 14) the phase sequence throughout this paper is such that phase 2 *leads* phase 1 by $2\pi/m$, phase 3 *leads* phase 2 by $2\pi/m$, and in general phase *y* leads phase $y-1$ by $2\pi/m$.

Appendix. Theorems Used in the Paper and Their Proof

Theorem I

If:

$$(a)\quad \boldsymbol{v}=v\epsilon^{j\alpha} \tag{65a}$$

$$(b_1)\quad |\beta_1|<|\beta_2|\leqq\pi \text{ or } (b_2)\quad 0<\beta_1=-\beta_2<\pi \tag{65b}$$

then

$$|v\epsilon^{j\alpha}+\epsilon^{j(\alpha+\beta_1)}-\epsilon^{j(\alpha+\beta_2)}|>v \tag{66}$$

Graphically this theorem states that if two vectors of unit length are respectively added and subtracted from a given vector $\boldsymbol{v}$, and if the added vector is closer to $\boldsymbol{v}$ than the subtracted vector then the result of the operation is an increase in the modulus of $\boldsymbol{v}$.

Proof: Write the left side of the inequality (66) in the following form:

$$|v\epsilon^{j\alpha}+\epsilon^{j(\alpha+\beta_1)}-\epsilon^{j(\alpha+\beta_2)}|=|\epsilon^{j\alpha}|\,|v+\epsilon^{j\beta_1}-\epsilon^{j\beta_2}| \tag{67a}$$

$$=|v+\epsilon^{j\beta_1}-\epsilon^{j\beta_2}| \tag{67b}$$

Squaring both sides of (67*b*) we have:

$$|v\epsilon^{j\alpha}+\epsilon^{j(\alpha+\beta_1)}-\epsilon^{j(\alpha+\beta_2)}|^2=|v+\epsilon^{j\beta_1}-\epsilon^{j\beta_2}|^2 \tag{68a}$$

$$=[v+(\cos\beta_1-\cos\beta_2)]^2+(\sin\beta_1-\sin\beta_2)^2 \tag{68b}$$

If hypothesis (b_1) of the theorem (see $65b_1$) is satisfied then $\cos\beta_1>\cos\beta_2$ and (68*b*) is greater v^2 which proves the inequality (66). On the other hand if $\beta_1=-\beta_2$ (see equation $65b_2$) then again (68*b*) is greater than v^2 and again the inequality (66) is satisfied. Thus the theorem is proved.

Theorem IIa

If

$$A=\sum_{k=1}^{u}\pm x_q^{a_{0k}} \tag{69}$$

where x_q is a primitive *n*th root of unity, *n* is even, $\pm x_q^{a_{0k}}$ are all different roots of unity, and $u<n$, then the maximum absolute value of *A* occurs when $x_q^{a_{0k}}$ are adjacent *n*th roots of unity or:

$$A_m=\sum_{k=1}^{u}x_q^{kb} \tag{70}$$

Proof: Since *n* is even we can make use of statement 7*a*, section 2, namely that each $-x_q$ is equal to some other *n*th root of unity x_r. Hence (69) may, without any loss of generality, be written in the following form:

$$A=\sum_{k=1}^{u}x_q^{c_{0k}} \tag{71}$$

where $x_q^{c_{0k}}$ are all different *n*th roots of unity.

Let A_m (figure 3) be the maximum vector obtained from (71) and let the angles made by the *n*th roots of unity with A_m be such that:

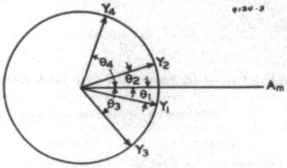

Figure 3. Maximum electromotive force per phase

$$|\theta_1|\leqq|\theta_2|\leqq|\theta_3|\leqq\ldots\leqq|\theta_n|\leqq\pi \tag{72}$$

Designate the *n*th root of unity x_r (see figure 3) by Y_s such that the subscript *s* of Y_s and the subscript *s* of θ_s correspond. Thus the *n*th root of unity Y_s makes an angle θ_s with the vector A_m.

If we can show that A_m is the sum of adjacent vectors or:

$$A_m=Y_1+Y_2+\ldots+Y_u \tag{73}$$

we shall have proved the theorem.

To show that A_m is represented by (73) assume that such is not the case. Then there must be two roots of unity Y_a and Y_b with $a<b$ such that Y_b is one of the vectors comprised in A_m and Y_a is not. This means that we can replace Y_b by Y_a and obtain a vector:

$$A_m-Y_b+Y_a=A\epsilon^{j\alpha}-\epsilon^{j(\alpha+\theta_b)}+\epsilon^{j(\alpha+\theta_a)} \tag{74a}$$

where

$$|\theta_a|<|\theta_b|\leqq\pi \text{ or } 0<|\theta_b|=|\theta_a|<\pi,\ \theta_b=-\theta_a \tag{74b}$$

Thus the conditions of theorem I are satisfied and

$$|A_m-Y_b+Y_a|>|A_m| \tag{75}$$

which is a contradiction of the fact that A_m (figure 3) is a maximum.

To show that A_m takes the form given in (70) observe that x_q in (71) is a primitive *n*th root of unity. Hence adjacent vectors take the form (see equation 4*a*) x_q^{kb}. Substituting $c_{0k}=kb$ in (71) we obtain (70).

Theorem IIb

If

$$A=\sum_{k=1}^{u}\pm x_q^{a_{0k}} \tag{76}$$

where x_q is a primitive *n*th root of unity, *n* is odd, *u* is odd, $x_q^{a_{0k}}$ are all different *n*th roots of unity and $u<n$, then the maximum absolute value of *A* occurs when *u* adjacent (2*n*)th roots of unity are added or:

$$A_m=\sum_{k=1}^{\frac{1}{2}(u-1)}x_q^{kb}-\sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)}x_q^{kb} \tag{77}$$

Proof: Referring to statement 8 of section 2 in the paper we conclude that the sum given in equation 76 consists of *u* terms each of which is a (2*n*)th root of unity. Hence we can apply theorem II*a* with 2*n* replacing *n* and obtain the result that the maximum absolute value of *A* in (76) occurs when *u* adjacent (2*n*)th roots of unity are added.

To show that A_m takes the form (77) observe that the terms of the sum in (76) are adjacent (2*n*)th roots of unity. Hence, for maximum *A*, equation 76 takes the form:

$$A_m=\sum_{r=1}^{u}(\epsilon^{j2\pi/2n})^r \tag{78}$$

In order to change (78) to the form (77) split (78) into two parts, depending on whether *r* is even or odd, as follows:

1. *r even.* Here replace *r* in (78) by 2*k* where *k* assumes successive integer values from 1 to $^1/_2(u-1)$ and obtain:

$$\sum_{k=1}^{\frac{1}{2}(u-1)}(\epsilon^{j2\pi/2n})^{2k}=\sum_{k=1}^{\frac{1}{2}(u-1)}(\epsilon^{j2\pi/n})^k$$

$$=\sum_{k=1}^{\frac{1}{2}(u-1)}x_q^{kb} \tag{79}$$

2. *r odd.* Here replace *r* in (78) by $(2t+1)$ where *t* assumes successive integer values from 0 to $^1/_2(u-1)$ and obtain

$$\sum_{t=0}^{\frac{1}{2}(u-1)}(\epsilon^{j2\pi/2n})^{(2t+1)}$$

$$=\epsilon^{j\pi}\sum_{t=0}^{\frac{1}{2}(u-1)}\epsilon^{j[(2t+1)/2n+\frac{1}{2}]2\pi} \tag{80a}$$

$$=-\sum_{t=0}^{\frac{1}{2}(u-1)}\epsilon^{j(2\pi/n)[t+\frac{1}{2}+n/2]} \tag{80b}$$

Now let $k=(t+{}^1/_2+n/2)$ and remember that $\epsilon^{j2\pi/n}=x_q^b$. Using this transformation (80*b*) becomes

$$\sum_{t=0}^{\frac{1}{2}(u-1)}(\epsilon^{j2\pi/2n})^{2t+1}=-\sum_{k=\frac{1}{2}(n+1)}^{\frac{1}{2}(n+u)}x_q^{kb} \tag{81}$$

Adding (79) and (81) we obtain (77).

Theorem III

If (1)

$$m=\prod_r m_r^{a_r} \text{ when } m\neq 4k+2 \tag{82a}$$

or

$$m=2\prod_r m_r^{a_r} \text{ when } m=4k+2 \tag{82b}$$

where $a_r>0$ and m_r are different prime numbers.

If (2)

$$p=\prod_r m_r^{b_r}p_2=p_1p_2 \tag{83a}$$

where

$$p_1=\prod_r m_r^{b_r} \tag{83b}$$

Table XVII. Conclusions Regarding n, Type, and s_0 Which Follow When p and s Satisfy Certain Conditions

Case	m	If		Then		
		p	s	n	Type	s_0
1	$2k+1$	Arbitrary	Divisible by 2^{d+1}	Even	B	$2s/n$
			Not divisible by 2^{d+1}	Odd	C	s/n
2	$4k+2$	Odd	Even	Even	A	s/n
			Odd	Odd	D_2	$[[s/2n]]$

NOTE. d is the highest power of 2 whic h is contained in p.

Table XVIII. Conclusions Regarding Relations Between c and p on the One Hand and c and s on the Other Hand Which Follow When Conditions a and b of Section 12 Are Satisfied. This Is a Proof of the Necessity of the Conditions

Case	m	p	s	n	Type	s_0	Conclusions From Condition b Namely That s_0/c Is an Integer
1	$2k+1$	Arbitrary	Divisible by 2^{d+1}	Even	B	$s/(n/2)=2p/q$	(1) $2p$ is divisible by c (2) s is divisible by c
			Not divisible by 2^{d+1}	Odd	C	$s/n=p/q$	(1) p is divisible by c. Hence $2p$ is divisible by c (2) s is divisible by c
2	$4k+2$	Odd	Even	Even	A	$s/n=p/q$	(1) p is divisible by c. Hence c is odd (2) s is divisible by c. Hence s is divisible by $2c$
		Even	Divisible by 2^{d+1}	Even	A	$s/n=p/q$	(1) p is divisible by c. Hence c is not divisible by 2^{d+1} (2) s is divisible by c. Hence s is divisible by $2c$
			Not divisible by 2^{d+1} but even	Odd	D_1	$s/2n=p/2q$	(1) p is divisible by $2c$. Hence p is divisible by c (2) s is divisible by $2c$
3	$4k$	Arbitrary	Even	Even	A	$s/n=p/q$	(1) p is divisible by c (2) s is divisible by c

Table XIX. Conclusions Regarding Type of Winding and Relation Between c and s_0 Which Follow When the Conditions of Table VIII Are Satisfied

Case	m	Condition of Table VIII	If		Then		
			p	s	Type	s_0	Other Conclusions
1	$2k+1$	$2p$ is divisible by c and s is divisible by c	Arbitrary	Divisible by 2^{d+1}	B	$2s/n$	c is a common divisor of $2p$ and s. Hence† it is a divisor of s_0
				Not divisible by 2^{d+1}	C	s/n	c is a common divisor‡ of p and s. Hence* c is a divisor of s_0
2	$4k+2$	p is divisible by c and s is divisible by $2c$. Hence s is even	Odd	Even	A	s/n	c is a common divisor of p and s. Hence* c is a divisor of s_0
			Even	Divisible by 2^{d+1}	A	s/n	c is a common divisor of p and s. Hence* c is a divisor of s_0
				Not divisible by 2^{d+1} but even	D_1	$s/2n$	c is a common divisor of p and $s/2$. Hence§ c is a divisor of s_0
3	$4k$	p is divisible by c and s is divisible by c	Arbitrary	Even	A	s/n	c is a common divisor of p and s. Hence* c is a divisor of s_0

* Since $n/q=s/p$ in its lowest terms therefore $s_0=s/n$ is the greatest common divisor of p and s. Therefore any common divisor of p and s is a divisor of s_0.

† c is a common divisor of $2p$ and s. Hence c is a divisor of their greatest common divisor. But this is $2s/n=s_0$. Hence c is a divisor of s_0.

‡ c is a divisor of s. Hence c is not divisible by 2^{d+1}. But c is a divisor of $2p$ which is divisible by 2^{d+1}. Hence c is a divisor of p.

§ c is a common divisor of p and $s/2$. Hence c is a divisor of their greatest common divisor. But this is $s/2n=s_0$. Therefore c is a divisor of s_0.

$b_r \geqq 0$, and p_2 does not contain m_k as factors.

If (3)

$$H=mp_1 \text{ when } m\neq 4k+2 \tag{84a}$$

$$=(m/2)p_1 \text{ when } m=4k+2 \tag{84b}$$

If (4)

$$n/q=s/p \text{ in its lowest terms.} \tag{85}$$

Then n is divisible by $\prod_r m_r^{a_r}$ if and only if:

$$s=HG,\ G \text{ any integer} \tag{86}$$

Proof: Write s in terms of the prime factors m_r as follows:

$$s=\prod_r m_r^{d_r} s_2=s_1 s_2 \tag{87}$$

where $d_r \geqq 0$ and s_2 does not contain m_r as a factor.

Divide (87) by (83*a*) and obtain:

$$s/p=\prod_r m_r^{(d_r-b_r)}(s_2/p_2)=n/q \tag{88}$$

Since neither s_2 nor p_2 contain m_r as prime factors and since $n/q=s/p$ in its reduced form therefore any prime factor m_r of n must be contained in the $\prod_r m_r^{(d_r-b_r)}$. This means that $(d_r-b_r)>0$. Hence a necessary and sufficient condition that n is divisible by $\prod_r m_r^{a_r}$ is:

$$d_r-b_r \geqq a_r \tag{89a}$$

or

$$d_r-b_r-a_r \geqq 0 \tag{89b}$$

Now write equation 87 in the following form:

$$s=\prod_r m_r^{a_r}\prod_r m_r^{b_r}\prod_r m_r^{(d_r-b_r-a_r)} s_2 \tag{90a}$$

$$=mp_1G=HG \text{ is } m\neq 4k+2 \tag{90b$_1$}$$

$$=(m/2)p_1G=HG \text{ if } m=4k+2 \tag{90b$_2$}$$

where

$$G=\prod_r m_r^{(d_r-b_r-a_r)} s_2 \tag{90c}$$

Since by (89*b*) $d_r-b_r-a_r \geqq 0$ therefore G is an integer. But by properly choosing d_r and s_2 in (90*c*) we can change the value of G in any arbitrary manner whatever. Hence G is an arbitrary integer and the theorem is proved.

Theorem IV

The conditions given in table VIII of section 12 are necessary and sufficient for the satisfaction of conditions *a* and *b* of that article.

Proof: It will be convenient to outline the proof in tabular form (table XVII).

From table XVII and conditions *a* and *b* of section 12 the following relations may be derived regarding types *A*, *B*, *C*, and D_1.

Type D_2 is necessarily omitted because of condition *a*.

In table XVIII we proved the necessity of the conditions given in table VIII. To prove the sufficiency of these conditions we assume that the conditions given in table VIII are satisfied and from this prove that conditions *a* and *b* of section 12 follow. This again will be arranged in tabular form (table XIX).

Notations

a = an integer (see equation 5), also the Fortescue operator
a_r = positive integers (see equation 63)
a_{jk} = integers (see equation 14)
A = type of winding (see table I)
$\mathbf{A}, \mathbf{A}_m$ = vectors (see theorems II*a* and II*b*)
b = an integer (see equation 4, also theorem II*a*)
b_r = non-negative integers (see equation 83)
B = type of winding (see table I)
c = number of circuits
c_r, c_r', c_r'' = integers (see tables II to V)
c_{0k} = integers (see theorem II*a*)
C = type of winding (see table I)
d = highest power of 2 contained in p (see note following table XVII)
d_r = non-negative integers (see equation 87)
D = type of winding (see table I), also total number of dead coils per phase (see equations 16, 27*a*)
D_1, D_2 = types of winding (see remarks following table I)
(D.W.) = dead-coil winding
$\mathbf{E}$ = vector electromotive force per phase
E = effective value of $\mathbf{E}$
$\mathbf{E}_0$ = electromotive force per coil side
$\mathbf{E}_{0N}$ = electromotive force per coil side due to the Nth harmonic
E_{aN} = algebraic sum of the Nth harmonic electromotive forces per phase
$\mathbf{E}_{cN}$ = vector sum of the Nth harmonic electromotive forces in two coil sides
E_{cN} = effective value of $\mathbf{E}_{cN}$
$E_{c'N}$ = algebraic sum of the Nth harmonic electromotive forces in two coil sides
$\mathbf{E}_{vN}$ = vector sum of the Nth harmonic electromotive forces per phase
E_{vN} = effective value of $\mathbf{E}_{vN}$
(F.W.) = fractional-slot winding
g = an integer
G = an integer (see equation 64)
h = total number of used slots per phase (see equations 16, 27)
H = an integer (see equation 64)
j = imaginary unit
k = an integer
k_{sN}, k_{WN} = distribution and winding pitch factors for the Nth harmonic
m = number of phases
m_k = prime factors of m or of $m/2$ (see equation 63)
n = an integer, defined by equation 9
n' = an integer (see equation 8)
N = number of harmonic
p = number of pairs of poles
p_1, p_2 = factors of p (see equation 83)
q = an integer, defined by equation 9
r = an integer
s = number of slots
s_1, s_2 = factors of s (see equation 87)
s_0 = number of slots which are displaced by a multiple of π from any given slot in any given phase (see equation 13)
s_0' = number of slots which are displaced by a multiple of π from any given slot (see equation 12)
s_{0u} = number of used slots per phase which are displaced by a multiple of π or 2π (see equation 25)
s_d = number of dead coils on each row of tables II to V (see equation 42)
t = an integer
u = number of different vectors per phase (see equation 26)
$\mathbf{v}$ = a vector (see equation 65)
x = unknown quantity or variable
$[\![x]\!]$ = bracket function
x_q = primitive nth root of unity
x_r = nth root of unity
y = an integer (see equations 39 and 40)
Y_s = vectors (see theorem II*a*)
α = argument of $\mathbf{v}$ (see equation 65)
α_q = argument of x_q (see equation 2), also slot pitch (see equation 11)
β_1, β_2 = angles (see theorem I)
β_y = arguments (see section 5*b*)
ϵ = base of Napierian logarithms
θ = an angle (see equation 46)
θ_r = angles (see theorem II*a*)
$\mu = m/2$ (see equation 20)
Π = symbol for product
σ = an integer (see equation 49)
ψ = per cent winding pitch

Analysis of Factors Which Influence the Application, Operation, and Design of Shunt-Capacitor Equipments Switched in Large Banks

J. W. BUTLER
MEMBER AIEE

THE application of shunt capacitors to distribution circuits has been well treated in the technical press. These papers have in general dealt with conditions obtaining when relatively small banks of capacitors are connected to the circuit 24 hours of the day. The increase in knowledge of the benefits afforded by capacitors through experience and analysis, coupled with the price reductions effected through advances in design and manufacture, has logically stimulated their use in fields where switching during the day, as governed by load and voltage conditions, is advantageous, desirable, and economically sound. These types of applications impose different duties upon the capacitors as well as upon the disconnecting equipments and associated devices, and the question naturally arises in the engineers' mind as to their effect upon the design and operation of the equipment. This paper offers a discussion and an analysis of the more pertinent of these problems. The conclusions drawn pertain in general to installations of 6,900 volts and below. The higher-voltage equipments may require additional considerations.

The interesting and encouraging conclusion is that in general the cases analyzed show that the duties imposed are well within the limitations of the standard product.

Conclusions

1. Means for limiting the magnitudes of inrush currents should not be required in general. Circuit breakers as normally applied from the dictates of other circuit requirements should suffice. If current-limiting features are required, inductance is much more effective than resistance and since reactors may be required in the larger installations for the improvement of wave form, they can also serve as the current limiters at the same time.

2. Transient capacitor voltages attending the energizing of large banks will never exceed twice the normal operating voltage of the capacitor. Voltage transients across the capacitor coincident with de-energizing will not exceed normal unless the voltage builds up due to restriking of the arc in the breaker, but this is considered a very remote possibility in equipments of 6,900 volts and below, which appear to have more possibilities in this country than those of higher voltage.

3. In the higher-voltage hand-operated (6,900 volt and up) delta-connected banks it is advisable to use oil fuse cutouts or three-phase air switches or oil circuit breakers instead of three single-phase air disconnects, to facilitate switching operations.

4. Wave form distortions accentuated by shunt capacitors can be reduced to a negligible amount by the judicious use of reactors in series with part of a group that is switched as a unit.

A—Inrush Currents When Energizing Capacitors

Since a capacitor exhibits zero impedance to the flow of current the instant voltage is applied, one may easily err in concluding that enormous transient currents flow during this energizing period. The energizing current for a single bank is always less than the short-circuit current value at that point and the circuit constants generally met in practice makes the same point hold true for multiple banks. In general these magnitudes of inrush current can be easily handled by the circuit control devices selected as dictated by other circuit characteristics.

1. SINGLE BANK

The transients attending the energizing of a single capacitor bank (figure 1) are representative of conditions when capacitors are connected permanently to the motor terminals and switched with the motor, or located out on a distribution feeder and are switched on and taken off as the system voltage or load conditions dictate. The maximum value of inrush current for this condition, derived in appendix *A*, is given by the expression

$$I_{max} = I_0\left(1+\sqrt{\frac{x_c}{x_L}}\right)$$

where x_c and x_L are the circuit capacitive and inductive reactances respectively and I_0 is normal capacitor current.

This expression is simple and conservative and should be useful in determining the duty on a given contactor or switch being used to control capacitors. If a more accurate and complete current picture is desired, equation 2 of appendix *A* could be used which gives instantaneous values as a function of time, including circuit resistance.

A typical application of a 180-kva 4,000-volt bank that may be switched out two miles from a 600-kva substation is analyzed and the results plotted in figure 2*a*. Here it is seen that the maximum current is about six times normal. The square root of the reactance ratio is 6.25, hence the above approximation gives a conservative inrush current value of 7.25 times normal.

2. PARALLEL BANKS

The energizing of a capacitor bank that is located very close to an energized bank (figure 3) results in considerably more current inrush than a single bank since there is very little impedance between the charged and uncharged banks. This circuit is analyzed in appendix *A* and equation 6 yields conservative results for the magnitude of the inrush current since the effect of resistance has been neglected.

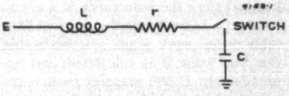

Figure 1. Circuit diagram representing a capacitor being energized through resistance and inductance

Normal circuit damping will reduce this value since skin effect increases the effective resistance considerably for the high-frequency components of current. The current magnitudes, however, neglecting damping, are not excessive or alarming, hence further refinement in the analysis is considered unnecessary.

Numerical results of a specific case, to which equation 6 pertains, are plotted as curve 1 in figure 4. This case is illustra-

Paper 39-158, recommended by the AIEE committee on power transmission and distribution, and presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27–29, 1939. Manuscript submitted July 29, 1939; made available for preprinting August 28, 1939; released for final publication November 13, 1939.

J. W. BUTLER is in the engineering division of the central-station department, General Electric Company, Schenectady, N. Y.

tive of four 1,080-kva banks installed at a point in a 4,000-volt system that will give a 150,000-kva short circuit. Such an installation might be made at a generation point to allow a certain generator to be shut down that would normally be run to carry reactive kilovolt-amperes or hold voltage during certain periods of the day.

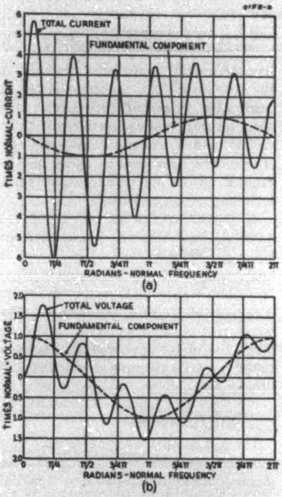

Figure 2. Energizing a single capacitor bank

(*a*)—Inrush current to capacitor
(*b*)—Circuit voltage at terminal of capacitor

The value of inductance (L_2) from the bus to each capacitor bank will probably never be less than 0.00377 ohm (10 microhenries) since the inductance of a circuit breaker, a current transformer, and little cable or bus work would amount to this. For this value it is calculated that approximately 11,500 amperes peak is obtained, which could be readily handled by the circuit breakers that would be normally applied at such a location.

3. Reduction of Inrush Currents

On rare occasions it may be desirable or necessary to limit or reduce the magnitude of these inrush currents, particularly in the larger multiple-bank arrangements. Since inductance or resistance may be used as the limiting agent each is analyzed in part 3 of appendix *A* and the numerical results for a particular installation are shown plotted in figure 4.

The curves in figure 4 show clearly the effectiveness of inductance and resistance in limiting the magnitude of this inrush current. For example, if it were desirable to limit this current to 10,000 amperes due to breaker limitations, or other reasons, it would require about 0.25 ohm of resistance while only 0.0062 ohm of inductive reactance would be required. Due to the continuous I^2R loss in the resistor it appears that inductance is the most economical and satisfactory way to reduce these currents when the occasion requires it. Resistance, however, could be switched in and then taken out with auxiliary equipment, but it would complicate the operation and arrangement. Other considerations as discussed in part *C* below, which may require the use of reactors should, in general, provide the necessary current limiting features in a practical case.

B—Transient Voltages Attending the Switching of Capacitors

The circuit voltage conditions resulting from the energizing and de-energizing of capacitor banks may be important from two standpoints. First, will the voltage be excessive for the capacitor and adjacent equipment and second, when energizing a bank will the voltage dip experienced while the capacitor is charging up the first half cycle be noticeable to consumers?

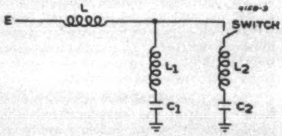

Figure 3. Circuit diagram representing the energizing of a capacitor bank adjacent to an already energized bank

1. Transient Voltages Above Normal

It has been spoken of before and is well recognized that a capacitor may be subjected to approximately twice normal voltage when energized. However, the conditions have not been fully determined that obtain when the supply circuit to which the capacitor is being connected, has a natural frequency of its own as well as a forced frequency voltage source.

(*a*) *Voltage Across Capacitor.* The equation for the voltage across a capacitor being energized from a bus on which there is already an energized bank is derived in appendix *B* and is given by equation 11.

Inspection of this equation shows that the coefficient of each term has in the denominator the product of the differences of two frequencies. If any two of these three frequencies approach each other, the coefficients could be numerically very large since resonance would be approached. In the normal application of capacitors however, these frequencies are widely separated. The lower natural frequency very rarely gets below 300 cycles per second and the higher frequency is usually above 2,000 cycles. These are both so far from the 60-cycle impressed frequency and from each other that the conclusion is drawn that the familiar twice-normal generalization also holds true for multiple banks of capacitors. In fact it may be shown that in all cases the voltage is no greater than twice the steady-state capacitor voltage. This is important, since these larger banks of capacitors are being considered more and more every day and fortunately the standard product is already designed for these transient voltages, hence this feature should not impede the development of this phase of the art.

(*b*) *Voltage Across Switch Contacts.* When de-energizing single or multiple capacitor banks, the analysis in appendix *B* further shows that with the normal sequence of contact opening and arc extinction, with no restriking of the arc the maximum voltage across the contacts of a three-pole breaker will be 3.46 times normal, and this occurs for delta-connected banks. Only twice-normal switch voltage can be obtained with wye neutral-grounded banks.

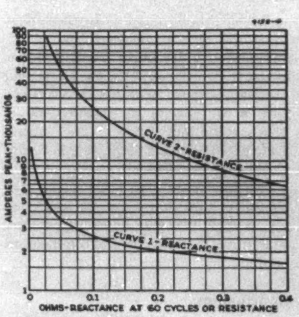

Figure 4. Effectiveness of resistance and reactance in reducing inrush currents to multiple capacitor banks

These duties are not considered abnormal since they are well within the normally encountered ranges of voltage recovery rates and magnitudes.

2. VOLTAGE DIP COINCIDENT WITH ENERGIZING A BANK

It is well known that when a capacitor is energized it appears as a short circuit until it accumulates a charge. Without further reasoning one may conclude that a voltage flicker would certainly be noticeable when throwing a bank on the line. The case discussed in part *A* under inrush currents of the 180-kva bank connected two miles from the substation is further analyzed to show the voltage conditions at the capacitor when it is energized. Equation 9, plotted for the constants applying, is shown in figure 2*b*. Here it is seen that the voltage is reduced to zero the instant the switch is closed, then as the capacitor charges up, the voltage is restored and it reaches normal value in about one-fourth of a natural frequency cycle. The natural frequency is 6.25 times normal, so normal voltage reappears in about 1/1,500 second which of course is a much faster recovery from zero than is experienced from a normal voltage zero at normal frequency.

Figure 2*b* further shows that the peak voltage reached is about 1.75 times normal, the reduction from twice normal being due to damping.

C—Miscellaneous Considerations

1. DE-ENERGIZING A THREE-PHASE BANK, ONE PHASE AT A TIME

Very often a bank of capacitors is switched manually with air-break disconnect switches or cutouts. In some cases it has been found difficult to extinguish the arc across the contacts of the switch, particularly in the case of the higher-voltage (6,900-volt) delta-connected banks.

In appendix *C* it is shown that the switch voltage of the first phase cleared in a delta bank may reach three times line-to-neutral voltage while the next phase opened may reach 3.46 *E*. In a wye neutral-grounded bank, it is shown that the maximum voltage is only twice normal. These values assume no building up of the voltage due to restriking of the arc across the switch.

To determine the effect of arc restriking on switch voltage, a typical installation was set up on the transient analyzer.[1] This gave accurate control of the restrike and it was found that with one restrike the switch voltages could be increased in each case (wye and delta) by a maximum of about 50 per cent.

From this it is seen that on occasion it may be desirable to switch the higher-voltage delta banks with oil fuse cutouts or oil circuit breakers instead of with single-phase air disconnecting devices if difficulty is experienced in breaking the charging current.

2. TRANSIENT VOLTAGES ON CURRENT-TRANSFORMER SECONDARIES

In the larger capacitor banks, it may be necessary to have current transformers in the circuit for control or indicating purposes. If adjacent capacitor banks are sufficiently closely coupled, the current transformers may represent a fair portion of the total inductance between the banks and as shown in appendix *C*, all the circuit voltage appears across these circuit inductances the instant the switch is closed. Hence a certain portion of this voltage appears across the current transformers and this voltage stepped up by the turn ratio may require special attention. Shunting resistors or current transformer surge absorbers should be used.

This is a rare phenomenon, but it is mentioned here in order to avoid confusion when it does arise.

3. MOTORS SWITCHED WITH CAPACITORS CONNECTED AT TERMINALS

The question of self-excitation of induction motors operating with capacitors has been adequately treated[2] and will be mentioned here only for completeness' sake. There are certain limits to the amount of capacitance that can be switched with motors to prevent abnormal self-excitation voltages and reference should be made to the appropriate literature for recommendations. It can be said, in general, that correcting the motor full-load power factor to 95 per cent will not result in unsatisfactory voltages.

Further, the application of capacitors in this manner changes the current required by the motor for a given load. It is necessary, therefore, to review the overload protection to make certain the motor is adequately protected after the installation of capacitors. It may at times be necessary to change the heater units in the motor thermal relays to conform to the reduced current drawn by the motor-capacitor combination.

4. IMPROVEMENT OF WAVE-FORM DISTORTIONS AMPLIFIED BY CAPACITORS

It is well known that any circuit combination of inductance and capacitance has a so-called natural frequency but this has no practical significance unless a voltage approaching that frequency is impressed upon the circuit. Experience and voltage measurements have shown that the fifth harmonic is generally the only harmonic voltage that is large enough to cause wave-form distortions of sufficient magnitude to require attention and these cases are rare. When capacitors are installed in large banks, primarily for voltage control, the wave distortion problem may require more attention than it has in the distribution field. The amount of capacitive kilovolt-amperes required to effect a four per cent rise in the 60-cycle voltage is about the amount to be in resonance with the fifth harmonic voltage, hence voltage improvements by capacitors approaching three or four per cent may need special attention.

A general method of using reactors for harmonic suppression is shown diagrammatically in figure 5. Here, a reactor is placed in series with a portion of the capacitor bank of sufficient ohmic value to cause that leg of the bank to be inductive to the harmonic current of the same magnitude as the other leg is capacitive, thus providing a wave trap. The total harmonic current taken from the line is then very small, just sufficient to supply the losses of the bank. The net corrective ability of the capacitors in series with the reactor is increased by the amount equal to the per cent voltage rise across the reactor. If the reactor is placed in series with one-half the bank, this increase in capacitive kilovolt-amperes amounts to 8.6 per cent. This scheme has been used on occasion in this country.

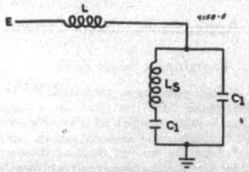

Figure 5. Circuit diagram illustrating the use of a reactor in series with part of a capacitor bank for harmonic current reduction

If it is not required practically to eliminate the flow of harmonic current in the line, the series reactor can be made a little smaller, of a size to cause that leg to have zero impedance, forming a resonant shunt, then the harmonic voltage will be effectively short-circuited at that point and the rest of the parallel banks are not affected by that particular har-

---

1. For all numbered references see list at end of paper.

monic. The harmonic current that flows will be that which can be forced through the system impedance by the harmonic voltage that was present on the system before the capacitors were installed. This does not necessarily represent much current since the harmonic voltage will generally be low, and the system impedance will be high for the harmonic. Assuming a five per cent fifth harmonic voltage (which is high average) the magnitude of the fifth-harmonic current would be 1 per cent of the available short-circuit current at that point. This scheme has been used to a great extent in Japan where large banks are used for system voltage control.[4]

Either method utilizes the capacitors in the bank for harmonic suppression as well as power-factor correction and they are mentioned here to acquaint the trade with available corrective methods if and when they are needed.

Appendix A. Inrush Currents

1. Energizing a Single Bank

A single-phase capacitor installation or a three-phase bank energized by a three-phase breaker on which all three poles close substantially simultaneously can be represented by the one-line diagram shown in figure 1. The maximum current flows in the capacitor when the switch is closed at the peak of the voltage wave corresponding to the application of a cos ωt voltage.

The current equation, in operational terms may be written as

$$I=\frac{E\cos\omega t}{r+pL+\dfrac{1}{pc}}$$

$$=\frac{E}{L}\,\frac{p\cos\omega t}{p^2+2\alpha p+\omega_0^2} \tag{1}$$

where

$$\omega_0^2=\frac{1}{Lc}\qquad \alpha=\frac{r}{2L}$$

The solution of (1) for the oscillatory case is

$$I=\frac{E}{Z}\left[\cos(\omega t-\psi)-\frac{\omega_0^2\epsilon^{-\alpha t}}{\omega\omega_1}\cos(\omega_1 t-\psi_1)\right] \tag{2}$$

where

$$\omega_1^2=\omega_0^2-\alpha^2$$

$$\psi=\tan^{-1}\frac{\omega^2-\omega_0^2}{2\alpha\omega}$$

$$\psi_1=\tan^{-1}\frac{\omega_0^2(\omega^2-\omega_0^2)-2\alpha^2\omega^2}{2\alpha\omega^2\omega_1}$$

$$Z=\left[\left(\omega L-\frac{1}{\omega c}\right)^2+r^2\right]^{1/2}$$

Neglecting the decrement and the effect of resistance on the natural frequency ω_0, then $\omega_0=\omega_1$ and the maximum current will be

$$I_{\max}=I_0\left(1+\frac{\omega_0}{\omega}\right) \tag{3}$$

but since

$$\frac{\omega_0}{\omega}=\frac{1}{\omega\sqrt{Lc}}=\sqrt{\frac{x_c}{x_L}}$$

a simpler expression can be written as

$$I_{\max}=I_0\left(1+\sqrt{\frac{x_c}{x_L}}\right) \tag{4}$$

$I_0=\dfrac{E}{Z}$ = normal steady-state current

where

$Z=x_c-x_L$

Thus a simple conservative expression is obtained for the maximum inrush current. The normal current I_0 is increased by a factor equal to unity plus the square root of the ratio of the capacitive and inductive reactances of the circuit.

2. Energizing a Bank Adjacent to an Energized Bank

Neglecting resistance gives conservative results and is simpler to handle analytically hence this assumption will be made in the analysis of figure 3. This circuit represents a capacitor bank C_2 being switched onto the bus, on which there is already an energized capacitor bank. The maximum current will flow in C_2 when the switch is closed at the peak of the voltage wave, which corresponds to maximum charge on C_1. The response of the circuit to the closing of the switch at this time, and considering the discharge from C_1 as well as the feed in from the system can be determined by simply applying a voltage across the switch equal to that existing across the switch before it was closed.* With this concept, the current flow into C_2 upon closing the switch can be written as

$$I_2=\frac{E'\cos\omega t}{\dfrac{pL\left(pL_1+\dfrac{1}{pc_1}\right)}{pL+pL_1+\dfrac{1}{pc_1}}+pL_2+\dfrac{1}{pC_2}}=$$

$$\frac{E'}{L_0}\left[\frac{p(p^2+\omega_3^2)\cos\omega t}{(p^2+\omega_1^2)(p^2+\omega_2^2)}\right] \tag{5}$$

for which the solution is

$$I=-\frac{E'}{L_0}\left[\frac{\omega(\omega_3^2-\omega^2)}{(\omega_1^2-\omega^2)(\omega_2^2-\omega^2)}\sin\omega t+\right.$$

$$\frac{\omega_1(\omega_3^2-\omega_1^2)}{(\omega^2-\omega_1^2)(\omega_2^2-\omega_1^2)}\sin\omega_1 t+$$

$$\left.\frac{\omega_2(\omega_3^2-\omega_2^2)}{(\omega^2-\omega_2^2)(\omega_1^2-\omega_2^2)}\sin\omega_2 t\right] \tag{6}$$

where

$$\omega_1^2=A-\sqrt{A^2-B^2}$$

$$\omega_2^2=A+\sqrt{A^2-B^2}$$

$$\omega_3^2=\frac{1}{c_1(L+L_1)}$$

$$A=\frac{1}{2}\,\frac{c_2(L+L_2)+c_1(L+L_1)}{c_1c_2(LL_1+LL_2+L_1L_2)}$$

$$B^2=\frac{1}{c_1c_2(L_1L+LL_2+L_1L_2)}$$

$$L_0=\frac{1}{\left[L_2+\dfrac{L_1L}{L_1+L}\right]}$$

E' = maximum voltage existing across switch before closing
L = system inductance per phase in henries
L_1 = inductance per phase from bus to capacitor bank c_1 including current transformers, disconnecting switches, breakers, and connections
L_2 = same as L_1 except applying to c_2
c_{1-2} = capacity per phase in farads

3. Reduction of Inrush Currents

(*a*). Inductance as the Limiter

The analysis of the circuit represented by figure 3 given in part 2 above can be used for evaluating the effectiveness of inductance in the capacitor leads for reducing the inrush current. In this analysis resistance is neglected so the limiting effect of the inductance alone is given.

As a numerical example, the case referred to in the body of the paper will be taken which is commensurate with a large installation that might be made at a generation point. Let

C_1 = three 1,080-kva 4,000-volt banks
= 540×10^{-6} farads per phase
C_2 = one 1,080-kva bank
= 180×10^{-6} farads per phase
L = system inductance corresponding to that which would give 150,000-kva short circuit at the capacitor location
= 0.1065 ohms at 60 cycles
= 0.283×10^{-3} henries
$L_1=\dfrac{L_2}{3}$ since it represents three banks in parallel

Substitution of these values in equation 6 and letting L_2 vary, curve 1 in figure 4 can be plotted. The maximum current is obtained when all three components of equation 6 are in phase hence the sum of the coefficients represents the maximum. L_2 is plotted as ohms at 60 cycles for ease of comparison.

(*b*). Resistance as the Limiter

The solution of the circuit shown in figure 6 for closing the switch at the peak of the voltage wave will give a conservative value of inrush current through the switch when resistance only is considered as limiting the current flow from the charged bank. By neglecting the inductance in each branch leading to the capacitor bank the full effect of the current-limiting value of the resistance is evidenced.

---

* This is known as Thevenin's theorem.

The maximum current which flows through the switch occurs at $t=0$ and is given by the simple expression

$$I_{\max}=\frac{E'}{r_1+r_2} \qquad (7)$$

Equation 7 can be used to evaluate the effectiveness of resistance in limiting current inrush through a breaker energizing a capacitor bank that is adjacent to an already energized bank.

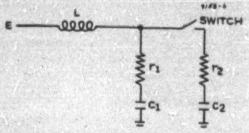

Figure 6. Circuit diagram of capacitors switched with resistors for limiting inrush currents

As a numerical example, the same case is considered as used above in evaluating the effectiveness of inductance.

Then

$$r_1=r_2/3$$

and varying r_1 over the same ohmic value as L_2 was varied, the results as shown in curve 2 of figure 4 are plotted.

Appendix B. Voltages Attending the Switching of Capacitors

1. Energizing a Single Capacitor Bank

The voltage at the terminals of a capacitor when it is energized may be readily obtained from the expression for current derived in appendix A, equation 1, such as

$$E_c=\frac{1}{pc}I$$

$$=\frac{E}{Lc}\,\frac{\cos \omega t}{p^2+2\alpha p+\omega_0^2} \qquad (8)$$

for which the solution is

$$E_c=\frac{EX_c}{Z}\left[\sin(\omega t-\psi)-\frac{\omega_0}{\omega_1}\epsilon^{-\alpha t}\times \sin(\omega_1 t-\psi_1')\right] \qquad (9)$$

$$x_c=\frac{1}{\omega c}$$

$$\psi_1'=\tan^{-1}\frac{\omega_1(\omega^2-\omega_0^2)}{\alpha(\omega^2+\omega_0^2)}$$

By neglecting damping

$$\omega_0=\omega_1$$

Then maximum transient voltage becomes

$$E_{c\max}=\frac{EX_c}{Z}2=\text{twice the operating voltage of capacitor}$$

2. Energizing a Bank Adjacent to an Energized Bank

The expression for the voltage at the terminals of the capacitor bank c_2, when the switch is closed in the circuit represented by figure 3 at the peak of the voltage, can be written directly from the expression for current given in equation 5 as

$$E_{c2}=\frac{1}{pc_2}I_2$$

$$=\frac{\omega_1^2\omega_2^2}{\omega_3^2}\,\frac{(p^2+\omega_3^2)}{(p^2+\omega_1^2)(p^2+\omega_2^2)}E'\cos\omega t \qquad (10)$$

for which the solution is

$$E_{c2}=E'\frac{\omega_1^2\omega_2^2}{\omega_3^2}\left[\frac{(\omega_3^2-\omega^2)}{(\omega_1^2-\omega^2)(\omega_2^2-\omega^2)}\cos\omega t+\frac{(\omega_3^2-\omega_1^2)}{(\omega^2-\omega_1^2)(\omega_2^2-\omega_1^2)}\cos\omega_1 t+\frac{(\omega_3^2-\omega_2^2)}{(\omega^2-\omega_2^2)(\omega_1^2-\omega_2^2)}\cos\omega_2 t\right] \qquad (11)$$

where

$$\frac{\omega_1^2\omega_2^2}{\omega_3^2}=\frac{1}{c_2L_0}$$

and the other terms are as defined in appendix A. At $t=0$, $E_{c2}=0$ which means that at that instant the fundamental-frequency voltage applied is opposed by the two natural-frequency voltages of the circuit. Hence by changing the sign of the two natural-frequency terms and adding all three coefficients, an expression for the maximum capacitor voltage is obtained, such as

$$E_{c2\max}=\frac{2E'\omega_1^2\omega_2^2(\omega_3^2-\omega^2)}{\omega_3^2(\omega_1^2-\omega^2)(\omega_2^2-\omega^2)} \qquad (12)$$

and since ω_1^2, ω_2^2, and ω_3^2 are all very much greater than ω^2,

$$E_{c2\max}\cong 2E'$$

which is twice the voltage that was applied to the oncoming bank.

3. De-energizing a Single Bank

The opening of a switch in a circuit is mathematically simulated by impressing through the switch the negative of the current that would be flowing if the switch were closed. Consider a single-phase or a three-phase wye neutral-grounded bank. With the above concept of opening a switch the expression for the voltage across the switch assuming the current goes out at a normal current zero, can be written as

$$E_{sw}=-I_0\sin\omega t\left[p(L_1+L)+\frac{1}{pc_1}\right] \qquad (13)$$

and solving

$$E_{sw}=E(E_{c1}-\cos\omega t) \qquad (14)$$

where,

$$E_{c1}=\frac{\omega_1^2}{\omega_1^2-\omega^2}=\text{voltage across the capacitor at the instant the switch is opened}$$

In general $\omega_1^2\gg\omega^2$ hence $E_{c1}=E$ and the maximum voltage across the switch in this case becomes approximately $2E$ if there is no restriking of the arc.

4. De-energizing a Bank Adjacent to an Energized Bank

Again considering a single phase on three-phase wye neutral-grounded bank (figure 3), and impressing $-I_0$ through the switch, the expression for the switch voltage may be written as

$$E_{sw}=-I_0Z(p)\sin\omega t$$

Where $Z(p)$ is the operational impedance of the circuit viewed from the switch as given in equation 5.

$$E_{sw}=-I_0\left[\frac{L_0(p^2+\omega_1^2)(p^2+\omega_2^2)}{p(p^2+\omega_3^2)}\right]\sin\omega t \qquad (15)$$

for which the solution is

$$E_{sw}=-I_0L_0\omega\left[\frac{\omega_3^4-\omega_3^2(\omega_1^2+\omega_2^2)+\omega_1^2\omega_2^2}{-\omega_3^2(\omega^2-\omega_3^2)}\times\cos\omega_3 t+\frac{\omega^4-\omega^2(\omega_1^2+\omega_2^2)+\omega_1^2\omega_2^2}{-\omega^2(\omega_3^2-\omega^2)}\times\cos\omega t+\frac{\omega_1^2\omega_2^2}{\omega_3^2\omega^2}\right] \qquad (16)$$

Equation 16 is composed of two oscillatory and one residual component. The maximum voltage will occur when they are all in phase, hence changing the sign of the oscillatory terms and adding their coefficients there is obtained an expression for the maximum voltage across the switch. Following out the above, there is finally

$$E_{sw}=E_{c2}\left(2-\frac{\omega^2\omega_3^2}{\omega_1^2\omega_2^2}\right) \qquad (17)$$

and since $\omega_1^2\omega_2^2\gg\omega^2\omega_3^2$ the maximum switch voltage comes out to be about twice that which was across the capacitor before the switch was opened.

5. De-energizing Delta-Connected Banks

Sections 3 and 4 above analyze the de-energizing of single-phase or three-phase wye neutral-grounded banks. The analysis of delta-connected banks requires separate consideration since the different phases cannot be considered as separate and independent. It is shown in appendix C that 180 degrees after the first phase of a delta bank opens, the switch voltage attains three times normal. However, when a three-phase breaker is used, the single-phase current flowing after the first phase clears, should clear 90 degrees later since it experiences a normal current zero at that time. This reduces the voltage across the first-phase-clearing contacts but if one of the two remaining contacts is slow to open or if one has a highly ionized path, two times line-to-line voltage or $3.46E$ can appear across the other.

Appendix C. Miscellaneous Considerations

1. Switch Voltages When One Phase at a Time Is Opened in a Three-Phase Installation

This condition may possibly occur in a three-phase interrupting device, or when three single pole air break disconnecting switches are used to control capacitor banks. In this analysis it is assumed that the switch opens at the normal current zero in which case the maximum residual charge is on the capacitors and further it is assumed there is no restriking of the arc.

(*a*). Wye-Connected Neutral-Grounded Capacitor Bank

Assuming the ground impedance from the capacitor bank to the nearest system ground point as negligible, the circuit in the clearing phase can be treated independently of the other phases. Hence the circuit of figure 1 and the analysis in section 3 of appendix *B* applies. Here it is shown that the switch voltage may reach twice normal.

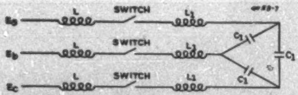

Figure 7. Circuit diagram of three-phase delta-connected capacitor controlled with three single-pole switches

(*b*). Delta-Connected Capacitors

Impressing the negative of the current through the switch, that would flow if it were closed, in the circuit shown in figure 7 and obtaining the expression for the voltage required to force this current through, the switch voltage is obtained as:

$$E_{sw}=-I_0\left[p(L+L_1)+p\left(\frac{L_1+L}{2}\right)+\frac{1}{2pc_1}\right]\sin\omega t \qquad (18)$$

solving and reducing

$$E_{sw}=\frac{3}{2}E(E_c-\cos\omega t) \qquad (19)$$

where

E = applied line-to-neutral voltage

$$=I_0\left[(L+L_1)\omega-\frac{1}{3c_1\omega}\right]$$

E_c = line-to-neutral voltage across capacitors before switch opened

$$=\frac{\omega_1^2}{\omega_1^2-\omega^2}$$

$$\omega_1^2=\frac{1}{3c_1(L_1+L)}$$

Neglecting the voltage rise through $L+L_1$ due to the capacitor current, the voltage E_c will be equal to E, hence when $\cos\omega t=-1$

$$E_{sw}=3E \qquad (20)$$

After the first phase is opened, there remains a single-phase circuit with a single-phase line-to-line voltage applied. Then opening the second phase at a normal current zero, two times line-to-line voltage or 3.46*E* will appear, 180 degrees later, across the switch. These voltages increase the degree of difficulty in de-energizing the higher-voltage and higher-current banks with single-phase air-break disconnecting switches.

2. Voltage Across Secondaries of Current Transformers

If adjacent capacitor banks are sufficiently closely coupled, the current-transformer inductances may represent a fair portion of the total inductance between the banks, in which case high transient voltages can appear across the current-transformer secondaries.

The voltage appearing across the inductance L_3 in figure 3 when the switch is closed is

$$E_{L3}=pL_3I_3 \qquad (21)$$

where I_3 is given by the operational equation (5) or its solution (6). At $t=0$ this becomes

$$E_{L3}=E'\frac{L_3}{L_0} \qquad (22)$$

Thus, it is seen that a good portion of E' might be impressed on the primaries of the current transformers, and this value stepped up through the secondaries may cause transient voltages requiring special attention. This phenomenon is truly rare since usually there are sufficient other inductances to share this burden, but it is mentioned here for the sake of completeness.

Dynamic Characteristics of a Single-Phase Induction Motor

E. B. KURTZ
FELLOW AIEE

SMALL-SIZE single-phase induction motors are used today principally on intermittent duty. In many cases this intermittent starting and stopping is automatically controlled. Loads are thus suddenly applied and as suddenly removed.

In order, therefore, to understand thoroughly the motor performance, it becomes necessary to observe its operation under impact conditions. Characteristics so obtained become the dynamic characteristics of the motor, as contrasted with its static characteristics.

It is the purpose of this paper, first, to outline the method and procedure employed in obtaining such characteristics, second, to present such characteristics for a typical single-phase repulsion-start induction motor, and third, to compare the mechanical output analytically determined with that actually recorded.

Rating of Motor. The motor used for this study, and the motor whose characteristics are shown hereafter, was rated as follows:

Three horsepower
110–220 volts
32.2–16.1 amperes
60 cycles
1,750 rpm

Laboratory Setup. Figure 1 shows a photograph of the laboratory test setup and figure 2 is a schematic diagram of the connections employed. In figure 1 the induction motor is shown directly coupled to a d-c generator which served as the load. The shunt field of this generator was separately excited, while the armature was directly connected to a resistance load. Closing or opening the field circuit would therefore apply or remove the load. A relay in the field circuit controlled by the oscillograph initiated the desired load impact.

Photoelectric Slip Meter. On the opposite end of the induction motor shaft the photoelectric slip meter, especially developed for these studies, is located. This slip meter[1] consists of two metal disks, each one having a series of small holes uniformly spaced on a circle. One of these disks is mounted on the shaft of the induction motor under test, while the other is mounted on the shaft of a small synchronous motor having the same synchronous speed as the induction motor. A lamp was so placed on one side of the pair of disks that its light would shine through corresponding holes in the two disks onto a photoelectric cell placed on the opposite side. The output of the cell is amplified and delivered to one of the galvanometer elements of the oscillograph.

Figure 1. View showing laboratory setup of single-phase induction motor study

Near end of motor shows special photoelectric slip meter developed for this test, and far end of motor shows d-c generator used as load. Oscillograph appears in the foreground

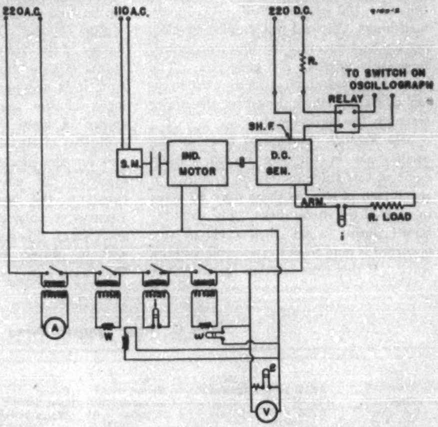

Figure 2. Schematic diagram of connections of the equipment shown in figure 1

Oscillograph. In the foreground of figure 1 also appears the six-element oscillograph employed in making the transient records during the load impacts. The following transients were simultaneously recorded: impressed voltage on motor, motor line current, motor input power, rotor slip, and generator armature current. The voltage record also served as the timing wave.

Application of 50 Per Cent Overload

Oscillogram. Figure 3 shows the oscillogram of the impressed voltage, line

Manuscript submitted May 31, 1939; made available for preprinting September 1, 1939; released for final publication November 21, 1939.

E. B. KURTZ is professor and head of the electrical engineering department, University of Iowa, Iowa City.

The author wishes to acknowledge the assistance of R. L. Witzke, research assistant in electrical engineering, University of Iowa, for assistance rendered in carrying out the investigation here reported.

[1] For numbered reference, see end of paper.

Figure 3. Oscillogram recorded when 150 per cent load was applied to the single-phase induction motor

	E(a-c) Volts	I(a-c) Amperes	W(a-c) Watts	E(d-c) Volts	I(d-c) Amperes
No load	232	8.35	600		
Load on	226	20.25	3,880	214	12

$i = 0.530$ ampere per millimeter
$e = 21.9$ volts per millimeter
$w = 168$ watts per millimeter
$I(d\text{-}c) = 0.320$ ampere per millimeter
Load resistance = 17.8 ohms

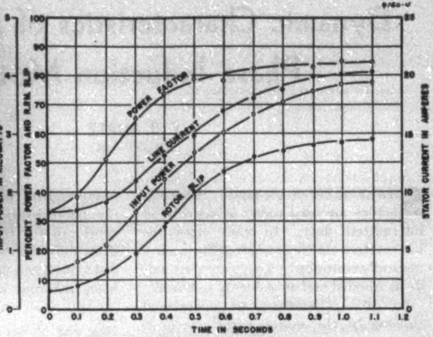

Figure 4. Graphs obtained from oscillogram (figure 3) showing variations of rotor slip, effective current, input power, and power factor during first second following the application of 150 per cent load

current, input power, rotor slip, and load variations recorded during the application of a 150 per cent load. As already mentioned, the load was applied by closing the field circuit of the directly coupled, separately excited, d-c generator. The instant of load application and the manner of its growth is shown by the upper trace on the oscillogram.

Slip Record. The lowest trace on the oscillogram is the slip record. Each cycle of this trace represents 1/30th of a revolution of slip, as there were 30 holes in each of the metal disks. The time interval during which each cycle of slip occurred is read from the 60-cycle voltage wave. If this time interval in seconds is denoted by t, the slip of the induction motor in revolutions per minute is $60/30t$ or $2/t$ rpm. From the readings for each cycle of slip the revolutions-per-minute slip of the rotor was computed. The calculated values of slip thus obtained are tabulated in table I and plotted in figure 4 for a period of approximately one second after the application of the load. It will be noted that at first there is little change in slip; this is followed by a rapid increase in slip, which in turn is followed by another period of decreasing change in slip as the final running speed is approached.

Line Current. To obtain the effective values of the line current at different instants of time during the transient period, it is necessary to sketch the envelopes of the maximum amplitudes as shown in figure 5. By measuring the ordinates of this envelope from the zero axis for any desired instant of time and applying the galvanometer calibration constant, the maximum amplitude in amperes is obtained. Assuming a sine-wave form, this must then be divided by $\sqrt{2}$ to obtain the effective current. Values so obtained are also tabulated in table I and plotted on figure 4 where comparison with the slip curve may be made. This comparison shows the current to vary approximately as the slip.

Power Input. Figure 5 also shows the envelope of the watt galvanometer deflections during the application of the load. By locating a locus midway between these two boundaries the average power variation is obtained. Applying the watt galvanometer calibration constant to the ordinates of this locus gives the average input power in watts at corresponding instants of time during the period of load impact. These values are also tabulated in table I and plotted in figure 4 alongside of the slip and current curves. The plotted graph shows the power to increase in value approximately as the slip, similar to the increase of current with slip.

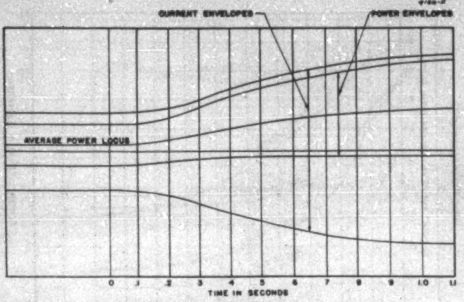

Figure 5. Boundaries of current and input power variations of oscillogram (figure 3) showing envelopes from which effective values of current and average power values were obtained

Locus drawn midway between upper and lower power envelopes gives average power ordinates. Amplitude of current variations must be divided by $\sqrt{2}$ to give effective values (sine wave assumed)

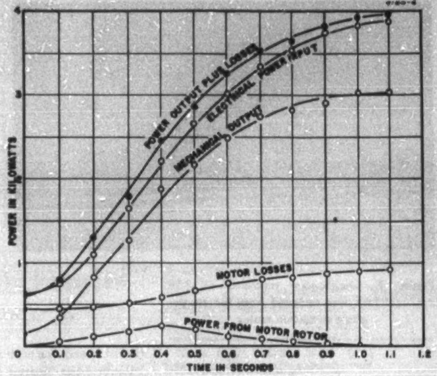

Figure 6. Graphs obtained from oscillogram (figure 3) showing variations in electrical input power, released rotor power, motor losses, and mechanical output, during first second following the application of approximately 150 per cent load

Power-Factor Variation. Having determined the effective value of line current and the average input power, the power factor may now be computed for corresponding instants of time, thus,

$$\text{p.f.} = \frac{P}{EI}$$

The effective value of impressed voltage was almost constant except for slight decreases during large inrushes in current. Computed values of power factor are given in column 6 of table I and are also plotted in figure 4. An inspection of the graph on this figure shows the power factor to start around 33 per cent at no load and to rise quite rapidly to approximately 85 per cent as the load is applied. After about 0.5 second the power factor has virtually reached its maximum value and is relatively constant during the period of further increase of load due to the approaching fixed relationship between current and power.

Mechanical Power Output. Ordinarily, under steady operating conditions, the output may be obtained directly by subtracting the motor losses from the input to the motor. Under transient conditions, however, where inertia effects must be considered, this is not possible. For example, sudden application of a load to an asynchronous motor, as in these studies, causes the rotor to slow up and consequently give up part of its kinetic energy. This kinetic energy then furnishes part of the power delivered to the motor shaft, thereby demanding a reduced electrical input. As soon as the new speed is reached this source of power disappears and the motor operates as under steady-state conditions.

As the purpose of this test was to determine the dynamic characteristics of the motor only, it was necessary to compute the kinetic effects of both motor and generator rotors separately. Ordinarily, all rotating equipment associated with the motor will contribute power in proportion to its moment of inertia. The equations used to compute either the power given up or absorbed by the rotating parts are given in the appendix. The essential data required for these calculations are the rate of change of speed at any given speed and the moment of inertia of the separate rotors. The first is obtained from the slip record and the second from comparison of frequency of oscillations with that of a body of calculable moment of inertia. Column 7 of table I gives the rotor power in watts, column 8 the motor losses, and column 9

No load	231	8.2	562		

i=0.530 amperes per millimeter
e=21.9 volts per millimeter
w=177 watts per millimeter
i(d-c)=0.320 amperes per millimeter
Load resistance=17.8 ohms

the resulting mechanical output, obtained as follows:

Mechanical output = electrical input ± rotor power − motor losses

For a reduction in speed the algebraic sign of rotor power is positive, and for a rise in speed the sign is negative. Column 10 gives the actual recorded power output. The calculated output appears to be slightly low for low values of output and slightly high for large values of output.

The variations in these quantities are brought out in figure 6. It is of interest to note that the sum of the mechanical output and losses is greater than the electrical power input throughout the period of application of load. This, of course, is as it should be since the rotor is slowing down during this period and is giving up part of its kinetic energy.

At about t=0.4 second, at which time the slope of the slip curve in figure 4 is greatest, the power given up by the rotor has its maximum value. At this moment the rotor is supplying 13 per cent of the power output. Near the beginning and end of the transient period the rotor speed is changing very little, causing the "output plus losses" and "electrical power input" curves to almost coincide.

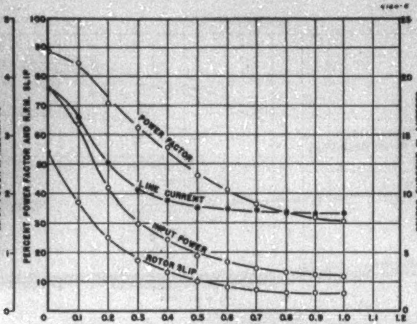

Figure 8. Graphs obtained from oscillogram (figure 7) showing variation of rotor slip, effective current, input power, and power factor during first second following the removal of approximately 150 per cent load

Removal of 150 Per Cent Load

Oscillogram. Figure 7 shows the oscillogram of the same quantities recorded during load application taken as the 50 per cent overload was removed. The load removal was accomplished by short-circuiting the field circuit of the d-c generator.

Figure 9. Graphs obtained from oscillogram (figure 7) showing variations in electrical input power, absorbed rotor power, motor losses, and mechanical output, during first second following removal of approximately 150 per cent load

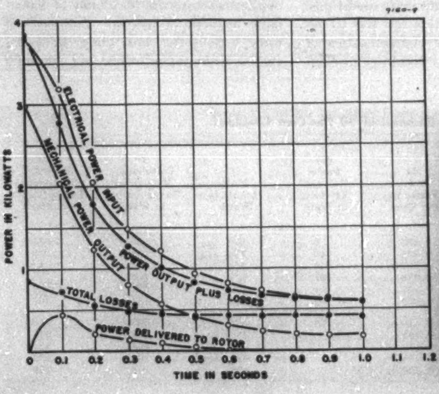

Figure 10. Oscillogram recorded as an excessive overload was suddenly applied to the single-phase induction motor

Extreme right end of oscillogram shows that governor has cut in the starting winding due to the large drop in speed

E(a-c) Volts	I(a-c) Amperes	W(a-c) Watts
233	8.25	600

i=3.03 amperes per millimeter
e=19.4 volts per millimeter
w=443 watts per millimeter
i(d-c)=0.808 ampere per millimeter
Load resistance=3.81 ohms

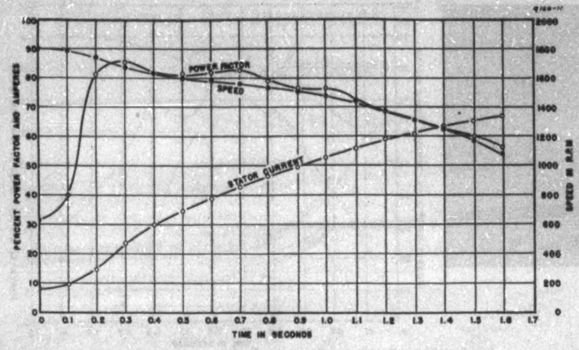

Figure 11. Graphs obtained from oscillogram (figure 10) showing variations in speed, power, power factor, and stator current during the first 1.6 seconds following the sudden application of an excessive load to the single-phase induction motor

The values tabulated in table II and plotted in figure 8 and figure 9 were obtained in the same manner as those of table I. In this case the electrical power input is always greater than the sum of the mechanical output and motor losses because of the absorption of kinetic energy by the rotor. During the removal of load the motor speed rises, which causes the motor rotor to absorb additional kinetic energy. The power input, hence, must be large enough to furnish this kinetic energy in addition to supplying the usual output and losses. Again, it will be observed that the calculated and recorded power outputs are in close agreement.

Load Application Versus Removal. In comparing the foregoing two sets of records it will be noted that the speed adjustment took place more promptly when the load was removed than when it was applied. Upon application of load the time of maximum speed reduction took place approximately 0.4 second after the load was applied, while the maximum speed rise took place approximately 0.1 second after the instant of load removal. Furthermore, the time interval during which most of the speed change took place was much shorter during the load removal than during application. This fact caused the rotor to absorb energy at a greater rate during removal than it released it during application. The computed values are 440 watts and 244 watts respectively. The 440 watts corresponds to 14 per cent of the motor input, and to 22 per cent of the mechanical power output.

Application of Excessive Overload

The oscillogram of figure 10 is a record of the same quantities heretofore considered when an excessive load is suddenly applied to the induction motor. In this case the load is large enough to cause the speed to drop to such a low value that the governor was caused to operate.

Inspection of figures 11 and 12 shows that the maximum power output obtainable from the motor is 6,280 watts. This is almost three times normal full-load value. Such a large output, of course, cannot be expected under steady-state conditions because approximately 1,300 watts of it is furnished by the kinetic energy of the rotor. During the entire period of load application the speed is decreasing rapidly, which makes it possible for the rotor to supply over one kilowatt of the mechanical output.

Further inspection shows that after $t=0.3$ second there is approximately a straight-line relationship between power factor and speed.

At the instant the governor operates, namely, $t=1.6$ second, the mechanical output has dropped to $1^1/_3$ times normal value, and the speed to approximately $^5/_8$th of rated speed. The motor losses, however, have increased to about seven kilowatts, which is equal to about $2^1/_3$ times the mechanical output. The line current at this instant is 67 amperes, which is about 4 times rated full-load current.

Starting From Standstill

For the sake of completeness the oscillogram, figure 13, showing the motor starting phenomena, is included. Figure 14 gives the characteristics as derived from the oscillogram.

At the instant of starting the motor draws a large starting current, 63 amperes, which decreases rapidly to 22 amperes at 0.6 second after starting. At this moment the governor operates, causing the motor to run as a squirrel-cage induction motor. Since the motor has only attained a speed of approximately 1,500 rpm at this moment another surge

Figure 12. Graphs obtained from oscillogram (figure 10) showing variations in electrical input power, released rotor power, motor losses, and mechanical output, during the first 1.6 seconds following the application of an excessive load

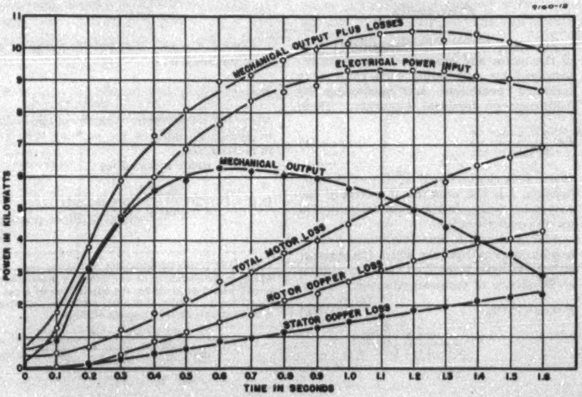

Figure 13. Oscillogram showing starting phenomena of the single phase, repulsion-start, induction motor

E(a-c) Volts	I(a-c) Amperes	W(a-c) Watts
233	8.3	600

$i = 1.90$ amperes per millimeter
$e = 19.4$ volts per millimeter
$w = 430$ watts per millimeter

of current takes place, reaching a magnitude of 59 amperes, which is almost equal to the initial starting current. This current, however, also drops off rapidly as the rated speed is approached. Full speed is reached in about 1.1 seconds after the line switch is closed.

Further inspection of figure 14 shows that the power fluctuates almost as widely as the current, attaining values in the neighborhood of 8,000 watts. The power factor starts at about 50 per cent, reaches a maximum value of about 80 per cent, and then drops to its normal no-load value of about 30 per cent.

Appendix

Moment of Inertia. The moments of inertia of the motor and generator rotors were determined by suspending each rotor as a torsional pendulum and measuring its frequency of torsional vibration. Then,

$$I = \frac{K}{4F^2\pi^2} \tag{1}$$

where K is the torsional rigidity of the suspension, I is the moment of inertia of the suspended body, and F is the frequency of its torsional vibration.

The constant K was determined by suspending a metal disk, for which the moment of inertia was calculated, and measuring its frequency of torsional vibration. Then,

$$K = 4\pi^2(F_d)^2 I_d \tag{2}$$

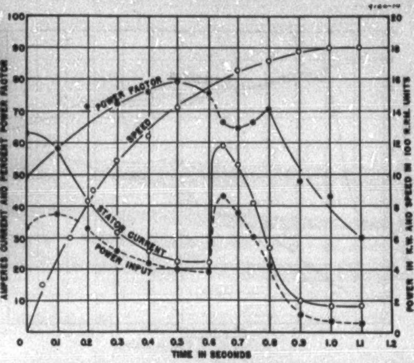

Figure 14. Starting characteristics of single-phase induction motor

where F_d is the frequency of vibration of the disk and I_d is the moment of inertia of the disk.

Equations 1 and 2 were then combined to give the expression for the rotor moment of inertia, thus,

$$I_R = \frac{4\pi^2 F_d^2 I_d}{4\pi^2 F_R^2} = \frac{F_d^2 I_d}{F_R^2} \tag{3}$$

The moment of inertia of a metal disk weighing 58 pounds was calculated and found to be 0.422 slug*-foot^2. This disk and the two rotors were each in turn suspended as torsional pendulums and their frequencies of vibration observed. These were as follows:

Metal disk	0.0881 oscillation per second
Motor rotor	0.198 oscillation per second
Generator rotor	0.310 oscillation per second

Then using equation 3:

$$I_{\text{motor rotor}} = \frac{(0.0881)^2}{(0.198)^2} \times 0.422 = 0.085 \text{ slug-foot}^2$$

and

$$I_{\text{generator rotor}} = \frac{(0.0881)^2}{(0.310)^2} \times 0.422 = 0.0341 \text{ slug-foot}^2$$

Kinetic Energy. The kinetic energy of a rotating body is:

$$\text{K.E.} = (1/2)I\omega^2 \text{ foot-pounds} \tag{4}$$

where I is the moment of inertia of the body in slug-feet^2 and ω is the angular velocity in radians/sec.

This is easily reduced to,

$$\text{K.E.} = (1/)2I\left(\frac{2\pi S}{60}\right)^2 \text{ foot-pounds} = 0.0055IS^2 \text{foot-pounds} \tag{5}$$

where S is the speed in revolutions per minute.

Multiplying equation 5 by $\frac{746}{550}$ gives,

$$\text{K.E.} = 0.00746\ IS^2 \text{ joules or watt-seconds}^{1} \tag{6}$$

Rotor Power. But

$$\text{Power} = \frac{d(\text{K.E.})}{dt} = 0.01492\ IS\frac{ds}{dt} \text{ watts} \tag{7}$$

The above power equation was used to calculate the power given up or absorbed by the motor and generator rotors. Values of S and ds/dt were taken from the slip curves which were plotted from the oscillographic slip records.

Substituting values of moment of inertia computed above, yields,

$$P_{\text{motor rotor}} = 0.01492 \times 0.085S\frac{ds}{dt} = 0.00128S\frac{ds}{dt} = \text{watts}$$

and

$$P_{\text{generator rotor}} = 0.01492 \times 0.0341S\frac{ds}{dt} = 0.000517S\frac{ds}{dt} = \text{watts}$$

* A slug is a unit of mass and equals the mass to which an acceleration of one foot per second per second would be given by the application of a one-pound force. Under standard conditions one slug of mass equals 32.1739 pounds of mass.

Electronic Measurement of Surge-Crest Voltages

J. M. BRYANT
MEMBER AIEE

M. NEWMAN
ASSOCIATE AIEE

Synopsis: An electronic voltmeter is developed for measuring surge-crest voltages, particularly in connection with laboratory lightning co-ordination tests of insulation breakdown. Simplicity of operation with high accuracy is obtained, as well as practical independence of time lags and of the form and duration of the waves encountered in engineering test work. A multiple bank of the crest-measuring units is applied in an instrument for giving directly the crest value for any particular surge in a single test to within one per cent accuracy. The instrument is applicable for general research on very short-time-duration surge-voltage phenomena as well as for convenient standardized laboratory testing of insulation.

QUICK determinations of crest surge potential values by a simple direct method are often desirable in the laboratory to supplement the cathode-ray oscillograph which records the entire surge phenomenon. The generally used sphere-gap method of potential measurement has, however, the disadvantages that a number of tests must be made in the process of adjusting for the breakdown distance, and sometimes the effect of time lag[1,2] of breakdown must be considered. In particular, it has been found in routine laboratory surge testing in connection with insulation co-ordination that sphere-gap measurements are erroneous for short duration potentials even with irradiation[3] of the gap when making tests of breakdown on the front of a sharply rising potential wave. Also on such chopped waves it is rather unlikely that the sphere-gap setting would be very close to the breakdown value and accordingly a large number of tests have to be made. It is at times essential that the actual breakdown voltage be recorded in a single test since some test objects can be broken down only once.

It was, therefore, considered desirable to develop an electronic potential-measuring device which would be about as simple as the spark gap, but which would give a direct peak reading in one test and would be practically independent of the test potential wave form and of time duration.

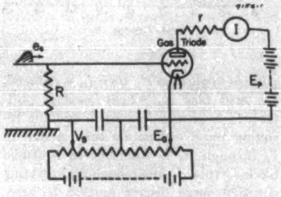

Figure 1. Measurement of positive surge-crest voltages by comparison with a negative bias on a grid-controlled gaseous-discharge tube

Surge-Crest Potential Measurements Principle, Using Gas Tubes

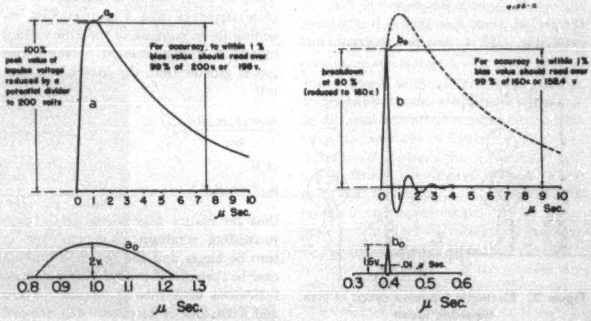
The bias-comparison method vacuum-tube crest voltmeter suggests itself as a possibility for measuring surge-crest voltages instead of steady-state crests if the vacuum tube is replaced by a grid-controlled gaseous tube. Thus in figure 1, with $V_s = 0$, the bias potential E_0 is adjusted just below the ionization discharge point for the tube. Then the additional negative bias voltage V_s is set roughly equal to the expected surge-crest value e_s and if e_s is greater positive than V_s, the grid rises above the critical ionization potential and the meter I indicates the resulting plate current due to neutralization of the space charge in the tube. The gaseous ionization process, once started, continues regardless of what later happens to the grid potential so that a permanent indication is obtained of when the crest surge value is greater or less than the bias V_s even though the surge is no longer present. The portion of the positive surge exceeding the negative bias potential serves as a triggering potential to set off the gaseous-discharge indication.

It is important that the triggering should respond even for very short surge duration. Two possible surge-potential waves whose crest-value measurements may be desired are shown in figure 2, for example. Curve 2*a* shows a standard 1x5-microsecond surge wave used in laboratory testing, reduced by means of a voltage divider to a value comparable to allowable grid potentials of the metering tube, for example, 200 volts; then if less than one per cent error is desired in the voltage indication the comparison bias potential would have to be at least

Figure 2. Typical surge-potential wave forms in laboratory test work

(*a*)—Standard 1x5-microsecond surge wave
(*b*)—Breakdown on the front of the wave

The crest values are measured accurately to within one per cent if a trip indication is obtained due to the resultant potential increments (a_0) and (b_0) of the part of the waves (*a*) and (*b*) exceeding their indicated comparison bias values



Paper 39-156, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE Great Lakes District meeting, Minneapolis, Minn., September 27-29, 1939. Manuscript submitted July 17, 1939; made available for preprinting September 5, 1939; released for final publication November 8, 1939.

198 volts. This leaves the very small resultant positive wave segment of two volts maximum magnitude and roughly 0.2-microsecond average time duration (as shown by a_0 in figure 2) for triggering. Curve *b* shows the same voltage wave with the breakdown of a test object occurring on the front of the test wave. Below it b_0 indicates the small resultant segment of 1.6 volts maximum magnitude and of the very short average time duration of less than 0.01 microsecond for which triggering should be completed to give measurement accuracies to within one per cent.

There is little doubt but that a gaseous tube could be designed to function as outlined above, for example, an ionization process in the Geiger counter[4] is initiated by the action of a very few ionizing electrons. Preliminary tests of available commercial gas tubes, however, indicated a dependence on surge duration such as to make doubtful a response to the tripping potentials of figure 2*b* within one per cent accuracy. The simple circuit of figure 1 would be quite suitable for a great deal of surge testing of greater time[5] duration; and in one application an assembly of ten surge-potential-measuring units using type 885 gas tubes was built up for measuring potentials at ten different points along a special transmission line. For greater sensitivity it was thought preferable to develop a scheme whereby the previous gas-ionization triggering action is obtained by a purely electronic relay method using available standard vacuum tubes.

An Electronic Relay of High Triggering Speed

A relay circuit* developed for very fast response to short-duration potentials is shown in figure 3. The high-vacuum triode *A* normally passes current I_A through R_2, and E_A is so adjusted that $E_A'-I_AR_2$ gives a net negative bias on the grid of triode *B* so that I_B is relatively negligible. If a negative current impulse is applied to R_1, then I_A is reduced, the grid bias $E_A'-I_AR_2$ becomes positive, I_B is greatly increased, and the resulting negative bias on tube *A* due to I_B through R_1 is sufficient to continue blocking tube *A* even though the initiating negative surge decays quickly to zero. Thus an ammeter in the plate circuit of tube *B* will show a permanent deflection after an impulsive tripping, while an ammeter in the plate circuit of tube *A* indicates an impulsive tripping by its new zero position. The instrument is reset by short-circuiting resistance R_1.

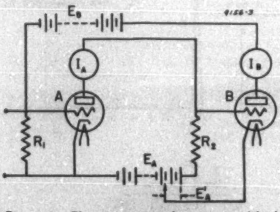

Figure 3. Electronic trip-relay circuit of high triggering speed

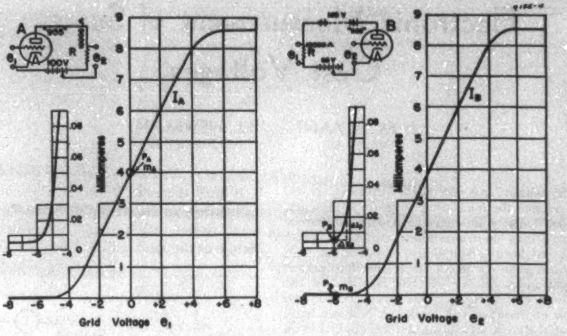

Figure 4. Characteristic operating conditions of the relay-circuit tubes, in the untripped position

The critical balance position as to which tube is passing current depends on the tube and circuit characteristics. The curves in figure 4 show the individual variations of the plate currents of tubes *A* and *B* as a function of grid voltages in their respective circuits Point P_A represents the untripped state of tube *A* plate current, and P_B that of tube *B*. An increase of the grid voltage e_2 of tube *B* by plus Δe_2 would cause a potential change of the grid of tube *A* equal to minus ΔI_BR_1, or minus $\Delta e_2m_BR_1$ where m_B denotes the slope $\Delta I_P/\Delta E_g$ at point P_B. This, in turn, causes a decrease in the plate current of tube *A* of $\Delta e_2m_BR_1m_A$ resulting in an increase of the grid voltage of tube *B* of $\Delta e_2m_BR_1m_AR_2$. Now if this last is greater than the initial Δe_2, that is if

$$\frac{\Delta e_2m_BR_1m_AR_2}{\Delta e_2}>1$$

or if

$$m_BR_1m_AR_2>1$$

then no matter how small Δe_2 is, each succeeding resultant increment will in turn be larger and the circuit will swing over to the reverse condition of a tripped indication with tube *B* passing current and with tube *A* blocked. The tripped position is stable, because of the high positive biasing resulting on tube *B* from the positive voltage E_A' (figure 3) with the disappearance of the negative biasing voltage I_AR_2, when I_A approaches zero.

The critical untripped balance position is obtained with the tube operating conditions of figure 4 just below the condition $m_BR_1m_AR_2=1$, by adjusting the value of E_A' in figure 3. It is apparent that the circuit might be adjusted so near the balance point that the slightest triggering impulse will cause the swing over. Actually there will be limitations, due to effects such as the Schottky[6] statistical variations of electron emission and temperature fluctuations, preventing too close approach to the critical balance position. However, the first tube *A* of the relay circuit acts also as an amplifier for the triggering impulse and, as may be seen in the following application of the relay circuit to potential measurements, very stable operation is possible, considerably below the balance point, with initiating impulses of even less than 10^{-8} second duration.

Surge-Potential Measurement With the Electronic Relay

A surge potential of positive polarity may be measured by determining the maximum additional negative bias it will balance on a screen-grid tube ahead of the relay circuit of figure 3, as shown in figure 5. Care must be taken in keeping the time constants determined by the stray capacitances as small as possible by careful choice and arrangement of the circuit elements to obtain short connecting leads and low interacting capacitances. For instance, the direct inclusion of a potential source E_B as in figure 3 for the relay circuit would introduce large capacitances to ground resulting in undesirably large circuit time constants. Instead, a small charged capacitor C_B, figure 5, furnishes a stable potential source in the transient process, during which the charging resistances r effectively isolate the capacitances of the supply source. The first tube, which compares the applied surge against its grid bias potential, must have a screened grid to prevent direct capacity transfer of the surge to the relay circuit through the tube grid-plate capacitance.

---

* Similar circuits in which one tube blocks another in a reversible manner have been used in other applications; some of the earliest are by W. H. Eccles, and F. W. Jordan, *Radio Review*, volume 1, 1919, page 143, and by L. B. Turner, *Radio Review*, volume 1, 1920, page 317. Another application of a similar circuit was made by K. J. Sixtus and L. Tonks, *Physical Review*, volume 37, 1931, page 935, for measuring time intervals of the order of 10^{-4} second.

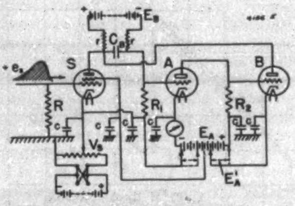

Figure 5. Electronic-relay surge-crest-voltmeter circuit diagram

Constants of the standard tube unit:

S—Type 36 tube
A, B—Type 37 tubes
R—1 megohm
R_1—10,000 ohms
R_2—17,500 ohms
r—15,000 ohms
C_B—0.001 microfarad
C—0.1 microfarad
E_A—220 volts
E_A'—120 ± 10 volts
E_B—320 volts

To reduce the vacuum-tube capacitances to a minimum, "acorn" type 954 and 955 tubes were used in the first experimental unit. It was found possible to substitute lower-cost standard radio tubes of type 36 and 37 and retain sufficiently high tripping sensitivity. Other types combining the functions of several tubes in one could be used, but the reliability and economy of modern vacuum tubes is such that the number of tubes is not of primary importance.

A Direct-Reading Surge-Crest Instrument

The single-unit vacuum-tube instrument is free from ionization difficulties, but the need for several adjustments still remains in order accurately to find the crest value by the trial method of adjustment. In addition, sometimes, as in testing an object which can break down only once, or in the testing of objects whose characteristics may vary with a large number of potential applications, it is desirable to have an instrument which will give direct readings on the potential application for which the crest value is required. A direct reading may be obtained with the bias comparison type of surge-crest meter previously considered if a number of units are used with the individual biases adjusted in regular steps to cover the range of voltages expected. The accuracy will, of course, now depend on the range of the biasing potentials in relation to the measured voltage value, as well as on the inherent accuracies of the individual voltage-measuring units. Such an instrument is shown in figure 6 which is composed of ten separate surge voltmeter circuits like figure 5, operating on individual power supplies, but connected to a common control board, thus allowing convenient change of the ranges of the regularly stepped biasing potentials.

It is generally desirable that the surge potentials be measured with reference to the ground frame of the instrument as zero potential. Consequently, in order to allow variations of the bias of any of the units independently, each unit is self-contained with its power supply quite separate. Each individual unit has the same circuit, shown in figure 5, and uses ordinary standard vacuum tubes. The potentials E_A and E_B are supplied, however, by two individual filtered rectifier circuits in each unit; the stability of the trip circuit is sufficient so that no trouble is encountered due to slight voltage variations in the regular power supply mains. The bias battery voltage, V_B, is checked by meter *A* in figure 6.

In operation the instrument with switch *R* (figure 6) in neutral position gives indications of the surge voltage in ten per cent steps of its range. After any indication the instrument is reset simply by depressing switch *S*. The instrument is changed to indicate one per cent steps by depressing switch *R* which shifts the bias of the component units to one per cent bias steps plus a common biasing voltage adjusted for the ten units simultaneously by a single tap switch to the nearest ten per cent step indication of the first run. Then in a second run the voltage can be determined to within one per cent. If the breakdown voltage of some test object is known approximately, as is often the case, to within ten per cent, then it is possible to obtain the actual breakdown voltage value to within one per cent in a single test.

Experimental Precision of the Surge Voltmeter

Verification of the accuracy of the electronic trip-circuit surge voltmeter on short-duration waves required the design of an accurate surge-voltage calibration circuit. A direct comparison with some other method of measuring surge voltages was not possible because neither of the commonly used methods of a carefully irradiated spark gap nor the usual cathode-ray oscillograph could be depended on to within one per cent accuracy in the case of the very short duration potentials encountered. In order to produce known surge potentials to within about one per cent calibration accuracy, an automatic-control impulse circuit was built, as indicated in figure 7. This control circuit determines accurately and automatically the desired voltage of the capacitor *C* before it is discharged to produce the surge wave. The surge peak potential $e^{\max}$ is directly a function of the initial charge potential *E*, which is accurately known. If the impulse-circuit constants are such that oscillations are well damped (roughly if $Z \leqq {}^1/_2 \sqrt{L_s/C_s}$,

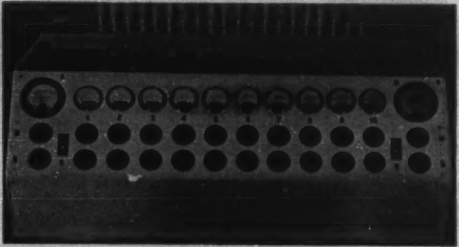

Figure 6. Direct-reading surge-crest voltmeter instrument

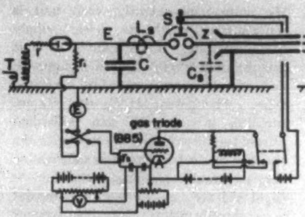

Figure 7. Surge-generating circuit used in calibration tests, with automatic control of voltage by a gas tube relay arrangement

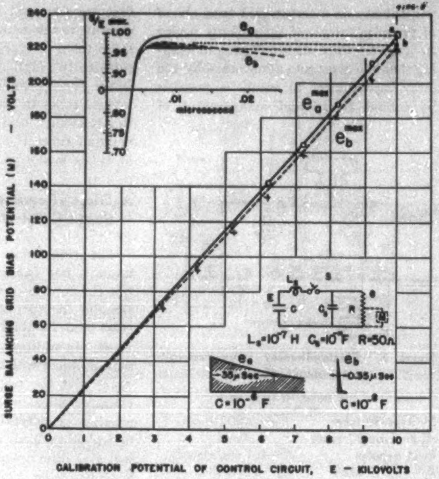

Figure 8. Experimental test of the accuracy of the electronic-relay-type surge-crest voltmeter

The circles indicate the experimentally obtained readings of the crest voltmeter for the wave (e_a) and should lie on the straight line giving the theoretical variation of (e_a^{max}) as a function of E

Similarly, the crosses obtained for (e_b) should lie on the dashed line. The deviations from the respective lines indicate the errors to be within one per cent for wave e_a, and within two per cent for wave e_b

which is the case in the circuits of figures 7 and 8) the surge peak potential reaches closely the same value as the initial potential of the capacitor C, providing the capacitance C is relatively large. This is illustrated by the curve e_a in the upper insert of figure 8; which is calculated for the given circuit constants with $C=1$ microfarad. Thus, for the wave e_a, it is established that the surge-crest value is practically the same as the potential of the capacitor C just *before* switch S closes; this gives a surge voltage whose crest values are known to be the d-c calibration potentials E for the control circuit.

The direct-reading voltmeter of figure 6 is connected to a section of R acting as a voltage divider in the position indicated by M in figure 8. For the wave e_a, a control setting of $E=10$ kv gives a surge crest known mathematically, by the previous analysis, to be very closely 10 kv; the corresponding bias reading on the crest voltmeter was found to be 228 volts. This experimental point was checked with other large values of C from one-half to four microfarads, which all gave the same e^{max}/E very closely to unity. These preliminary tests established the voltage divider ratio to be 228/10,000. A straight line drawn through the origin from the 10-kv bias reading, indicated by the square on figure 8, should give the theoretical true curve for the relation of the meter bias values to the surge-crest values, which in the case of the wave form e_a are the same as the potentials E. The relationship should be a straight line because the only circuit element which cannot be considered truly constant, the control spark-gap resistance which varies as a function of the current passed,[7] is reduced to a negligible factor by operation of the gap at high gas pressures. The surge-crest potentials, therefore, vary in magnitude directly as the calibrating potential E. Thus, if the surge-voltmeter bias values correctly indicate the peak value of e_a, they should lie on that straight line as E is varied; and the fact that the experimentally found points indicated by the circles do lie closely on that line proves an accuracy of within one per cent for a surge wave of the type e_a shown in the lower insert of figure 8. Thus it is directly determined by experiment that the surge voltmeter will record the standard 40-microsecond duration wave peak values to well within one per cent accuracy. Quite apparently also the accuracy on the standard 1x5-microsecond wave of figure 2*a* could, by comparison, also be expected to be within one per cent. The next test was made with an extremely short duration wave of 0.35 microsecond to half value (e_b) to correspond with the chopped test wave resultant of figure 2*b*. The short wave e_b of figure 8 is obtained by reducing the capacitance of C to a value of 10^{-8} farad; and now it is found by calculation[8] that the theoretical value of e^{max}/E is only 0.98 instead of closely unity as before. Therefore, the line on which the new experimental points should lie (for e_b) is the dashed line crossing the 10-kv ordinate at point *b*, corresponding to $e^{max}/E=0.98$, as indicated in figure 8. It will be seen that the experimental points for e_b, indicated by crosses, although in fair agreement, all lie somewhat below the theoretical dashed line. It is quite probable that for the very short duration peak of e_b an appreciable voltage magnitude is required to complete the tripping process, as indicated by the cross-sectioned part of the peak of e_b in the upper insert of figure 8. This indicates that for a wave as short as e_b the error may go as high as two per cent, although, knowing the character of the wave, a partial correction may be made allowing for that type of discrepancy. By comparing the above results with the requirements indicated in figure 2 and in previous discussion, it may be concluded that the surge voltmeter will readily measure peak potentials to within two per cent accuracy on any of the possible waves usually encountered in engineering laboratory testing. With some care in adjusting the ratio range so that the measured peak will fall near the full scale of the instrument, accuracies of one per cent are apparently possible.

It is of interest to note that the experimentally obtained accuracies include the accuracy of the control circuit of the impulse generator. The control circuit accuracy must, therefore, also have been better than within one per cent error. Detailed calculation including the distributed constants of large impulse generators[9] have shown the same direct proportionality of the resultant surge voltage to the charging voltage, providing the initiation of the surge generator is accomplished by simultaneous timing impulses applied at a number of the surge-generator intermediate gaps to insure uniform initiation. The same method of control is, therefore, applicable to large surge generators and would indeed be advisable for front-of-wave testing where it is essential to maintain the same wave-front form.

In the measurement of high surge potentials of short duration, the voltage divider used must be carefully designed[10,11] so as not to introduce appreciable errors. In the tests of this paper a resistance divider was used in shunt with a shielding capacitance divider of the same ratio.

Throughout the discussion the crest voltmeter was considered for only positive polarity surges. Experiments have indicated the adaptability of the instrument for negative polarities as well by introducing a switching arrangement to change the circuit to the dashed connection shown in figure 5. But it was found simpler and sufficient to leave the crest voltmeter responsive to only positive polarity and when necessary reverse the polarity of a negative surge in the coupling transmission-line system.

The crest voltmeter instrument has been found also particularly useful in the direct measurement of surge-current crests in conjunction with proper shunts. Other applications have been made which indicate the rapidity of response of the crest voltmeter, as, for example, in the measurement of time lags of electrical breakdown less than 10^{-8} second duration described in another paper.[12]

Summary

An electronic peak voltmeter is developed for measuring surge voltages of short duration. Simplicity of operation is obtained with practical independence of time lags and of formative-time ionization difficulties, such as those encountered by the usual spark-gap method, in the measurement of short-duration potentials in front-of-the-wave breakdown tests.

Direct recording of any particular surge-crest potential, without the requirement of a large number of tests, is obtained in an instrument assembly composed of ten surge-crest voltmeter units biased in regularly stepped intervals. The entire voltage range can be covered in ten per cent steps, and when the voltage is known to within ten per cent the instrument is switchable to cover any required ten per cent range in steps of one per cent.

The direct-recording surge-crest voltmeter was tested experimentally. A specially designed automatically controlled surge-generating circuit was used for calibration purposes. Accuracies of within one per cent were determined possible for measurements on the standard 1x5-microsecond and $1\frac{1}{2}$x40-microsecond surge waves. Less than two per cent errors were obtained even on a very short duration potential wave of less than 0.4 microsecond to half value, corresponding to the chopped waves resulting from front-of-wave breakdown.

With properly designed voltage dividers, the electronic peak voltmeter instrument may be used conveniently in place of the spark-gap method, particularly for very high impulse voltages, where the spheres and spacings become large and time lag difficulties are encountered for short duration potentials with the spark-gap voltmeter. By controlling also the output voltage of the impulse generator, after the manner used in the calibration circuit of this paper, it may be possible to obtain surge-voltage measurements of closely reproducible character, with over-all accuracy of measurements to within one or two per cent on general test work in the laboratory.

Measurement of Very Short Time Lags

J. M. BRYANT

M. NEWMAN
ASSOCIATE AIEE

Synopsis: Direct-reading measurements of time lag in surge circuits were obtained by an electronic relay method using two surge waves on a calibrated artificial transmission line. Time definitions were obtainable down to 10^{-9} second. Although a cathode-ray oscillograph was designed to give comparable recording speeds, the electronic relay method had advantages of simplicity and direct readings, making it a useful auxiliary instrument for rapid work.

THE time lag of electrical breakdown of various air gaps and solid insulations is of particular importance in co-ordination[1] of insulation for transient lightning surges. Generally, time lag of breakdown is in part a function of chance ionization conditions in the breakdown path and therefore the measurements become often of a statistical nature.[2] Thus, where a large number of measurements are to be made, a direct method giving immediate readings free from the delays of photographic development would be a valuable auxiliary to cathode-ray oscillography.

In a previous paper[3] an electronic surge-crest voltmeter is described. Using such voltmeter units to determine the voltages of an incoming surge wave at definite time intervals in relation to another reference timing wave it is possible readily to make direct determinations of time lags down to 10^{-8} second with accuracy of definition of 10^{-9} second.

The Method of Measuring Time Lags

The element of time is introduced by means of an electrical transmission line on which the velocity of surge travel is easily calculable. The general principle of the time lag measurements is shown in figures 1 and 2, each of which shows the time relations of the traveling waves at four successive instants.

At intervals of distance along the transmission line corresponding to the desired time of travel positions, there are placed the series of electronic potential recording instruments, 1, 2, 3, . . . to 10, which are biased to respond to positive impulses of very short time duration and do not respond to negative potentials. At one end of the line there is shown arriving the surge S of positive polarity, and at the other end the negative timing impulse, T, which is synchronized in relation to the potential which causes surge S. Figure 1 indicates conditions where there is no time lag between the arrival of T and S at their respective ends of the line; the two waves will just meet at the center as at B and meters 10, 9, . . . to 6 inclusive will be tripped by the passage of the positive surge S. The rest of the meters will remain untripped because due to the large negative timing surge T there is only a dip in the negative potential as shown in D, but no net positive impulse resulting from S beyond the meeting point.

In the study of time-lag characteristics of a gap, the positive surge S is produced by the breakdown of the gap, and the time lag t caused by the formative spark process delays the arrival of the surge S in relation to the timing wave T, as indicated in figure 2A. Then, as may be seen in figure 2B, when the timing wave T arrives at the center, the surge S will be delayed by the distance $d=vt$, where v is the velocity of the wave travel along the line. The two waves will now meet at $d/2$ to the right of the center, and the meters 6 and 7 in that interval will also be untripped. It is clear, therefore, that the number of meters remaining un-

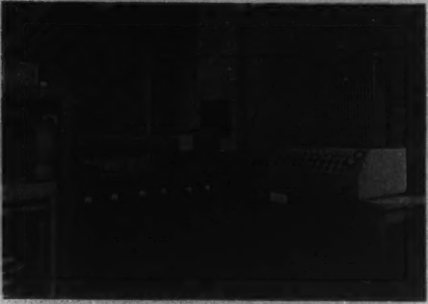

Figure 4. View showing the "dual wave" time-lag measuring instrument and the cathode-ray oscillograph interconnected at the middle point of the transmission line for comparative measurements within the oscillograph range

tripped on the positive side of the electrical center (the meeting point in the case of zero time lag) indicates the magnitude of the time lag, which determines the distance that the blocking negative timing surge *T* had a chance to travel in the additional interval of half the time lag of arrival of the surge *S*, before meeting the latter.

The oscillograms of figure 3 give experimental illustration of the wave relationships, but on a variable-time fixed-point basis as compared with the space distribution of figures 1 and 2. The cathode-ray oscillograph recorded the voltage at the electrical center of the artificial transmission line. Oscillogram of insert *a* gives just wave *S* coming in from the right side of the line with the other end short-circuited. Oscillogram *b* gives the wave *T* coming from the left side of the line with the right-side short-circuited. And oscillogram *c* shows how both waves appear combined. With the oscillograph located at the electrical center the oscillograms give the correct time shift corresponding to the time lag involved; the electronic lag-measuring assembly functioned at the same time and gave a direct lag indication of 0.6 microsecond in agreement with the oscillograms. A photograph of the apparatus in figure 4 shows the interconnection of the cathode-ray oscillograph, the electronic instrument, and the artificial transmission line.

Short Time Lags

On the front of a steeply rising voltage wave the time lag of breakdown may be very short depending on how quickly overvoltages are reached. To study the characteristics of such breakdown two methods of approach are possible and the results of both together are necessary for a complete picture of the phenomena involved. Thus, first, to study the basic characteristics of time lag it is desirable to eliminate the applied voltage wave-shape variation as a factor by making the wave shape nearly rectangular and to study time lag as a function of overvoltage. Second, it is desirable to study the time lag under conditions often encountered under lightning surge conditions in practice, that is, time lag as a function of a voltage rising linearly with time.

In the first, more fundamental approach, recent work of a quantitative character on time lags has been done by A. Tilles[4] in the interval between 10^{-5} and one second for low overvoltages; while for higher overvoltages the short time lags between 10^{-9} and 10^{-6} second have been further investigated by H. J. White[5] and R. R. Wilson[6]. The work by Tilles was done for relatively long time lags with a highly accurate direct-reading scheme in which a vacuum tube acted as a valve charging a capacitor in the interval between the application of potential to the gap studied and breakdown of the gap.

The work with very short time lags by White and Wilson was done by using Kerr cell shutters operated by the voltage initiating breakdown. The arrival of voltage at the Kerr cell was delayed by a transmission line which was manually varied in length until the Kerr cell shutter closed just as the gap broke down. The Kerr cell methods necessitated considerable adjustment and a large number of tests, and since there were considerable discrepancies between different methods of applying the Kerr cell measurements, the dual-wave method of this paper was developed and applied to the direct measurement[7] of very short time lags.

Results in the measurement of very short time lags by the dual-wave method and by Kerr-cell methods are given in figure 5 with the respective circuit diagrams used. If one takes into account small errors inherent in the Kerr-cell measurement setups mentioned by White and Wilson in their own respective papers and discussions, the results by the Kerr-cell methods are brought into close agreement with each other and would fit much more closely to the dual-wave results.

Diagram *C* in figure 5 gives the setup used. The measurements were made for the case of a pair of polished brass spheres $^{3}/_{4}$ inch in diameter separated for 10,000-volt breakdown under steady-state potential, and with strong ultraviolet irradiation of the surfaces from a quartz mercury lamp at a distance of 2.5 inches from the gap. The kenotron supply metered by *V* in the diagram was used to note the effect of a steady partial approach voltage across the gap *g* prior to the impulse application. It is required to find the lag between the beginning of electrical breakdown *g* and the initial application of surge potential to *g*. Potential is applied to *g* through the closing of *S* when the impulse-generating capacitor reaches the desired value of voltage. As soon as *S* closes current flows through *Z* sending a negative surge down the transmission line; this serves as the timing wave *T* since it is the same wave causing breakdown of the gap. When the gap *g* breaks down current flows through the other end of *Z* in the opposite direction for a time depending on the distance *h*, sending a positive surge corresponding to the wave *S* of figure 2. The time lag between the two surges is directly recorded as previously discussed.

It is important that the potential applied to gap *g* be initially as nearly rectangular in form as possible if the time lags are to be a function of overvoltage only and not of wave front. To keep the transient spark resistance of the control switch gap *S* from flattening the wave front, the switching gap assembly was operated at high pressures of about 30 atmospheres in order to lower the spark resistance to a negligible value. The pressure-chamber assembly is connected directly to the transmission line and mounted on a tank inside of which the potential-supply capacitor is immersed under oil to keep the length and therefore the stray inductance of the connecting leads to a minimum.

The Time Intervals and Their Calibration

The time intervals are directly proportional to the electrical length of the artificial-transmission-line section between the recording meters. Different

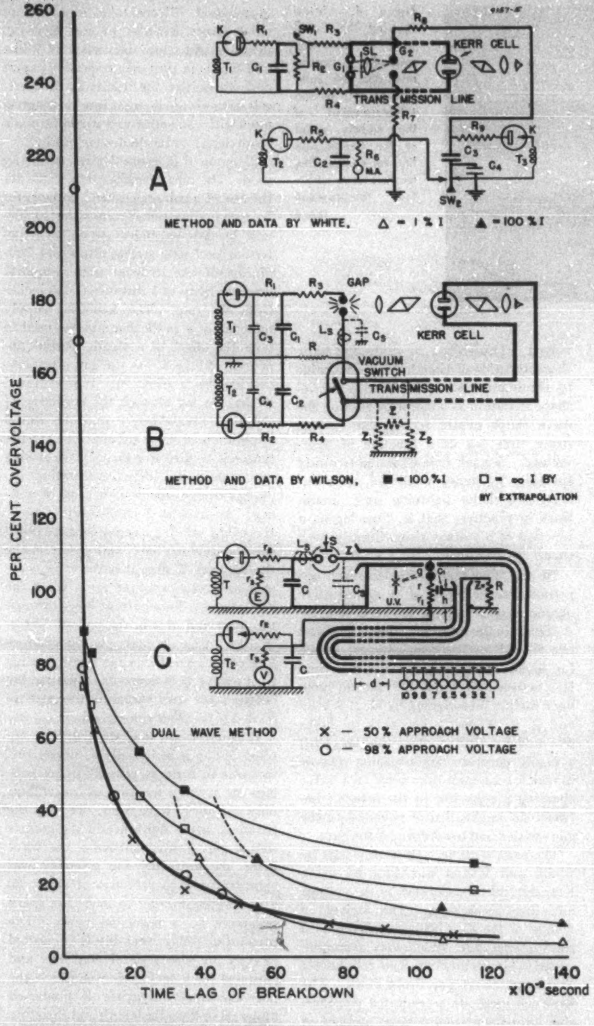

Figure 5. Time lag of spark breakdown as a function of over voltage for a short sphere gap with intense ultraviolet irradiation of the sphere surfaces

types of artificial lines were used for different time ranges. A transmission line covering the ranges of 1 to 10 and 10 to 100 microseconds was constructed using shielded sections of lumped inductance and capacitance. The transmission line used in obtaining the directly checking oscillogram of figure 3 covered the range of 0.1-microsecond units; that line was made in cable form by slipping rubber-covered wire inside small-diameter (one-quarter-inch) brass tubing. For shorter time lags, below 0.1 microsecond, the transmission line was made of concentric brass tubing with air dielectric throughout except for small centering washers of rubber. The transmission-line units were made into an assembly of 100 short lengths so designed that the inner pipes may be readily reconnected in relation to each other and the recording units. This transmission-line assembly is located (figure 4) just over the recording units of the electronic instrument, so that the coupling connection between selected points of the transmission line and the vacuum-tube control grids is kept very compact and does not affect appreciably the characteristics of the line. The connecting links and their shields were also designed to minimize any change in the transmission line characteristic; details of construction of the coupling arrangement are observable in figure 7, which shows a continuously variable section of transmission line built in the same manner.

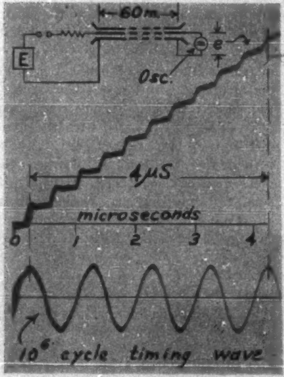

Figure 6. Calibration oscillogram of time of travel versus distance on a transmission line, recording the time for a given number of reflections on a given length of the line

The concentric-pipe assembly of figure 4 was designed to give a distance between recording units corresponding to time intervals of 0.01 microsecond on the basis of the waves traveling in this essentially air-dielectric cable at the velocity of light, or 3×10^{10} centimeters per second. A check was made by means of the cathode-ray oscillograph to determine whether the lengths including the effects of the couplings and supporting washers were correctly in agreement with the desired time interval.

The timing calibration on the concentric-pipe assembly was made on a large

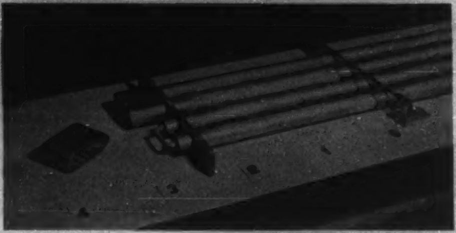

Figure 7. A telescoping variable-length transmission-line section calibrated in 10^{-9}-second units

number of line sections in series; a 0.01-microsecond section would be difficult to distinguish on a cathode-ray oscillogram, and consequently 20 such sections, or 60 meters, were taken in series. Furthermore, to obtain still greater calibration accuracy, the wave impedance, which in normal operation of the transmission-line system prevents reflections, was removed and the line was connected impulsively to a high-voltage source through a high resistance. The circuit diagram and the resulting oscillographic record of the voltage appearing at the open end are shown in figure 6. The first potential wave should arrive at the open end of the 60-meter line in a time $\frac{d}{v}$, or $\frac{6{,}000 \text{ cm}}{3\times10 \text{ cm/sec}} =$ 0.2 microsecond. At the open end this wave reflects and travels back to the resistance end in 0.2 microsecond. At the resistance end the resistance is so high as to present practically an open-circuit condition, and the first reflected wave is again reflected back; and in another 0.2 microsecond, or a total of 0.4 microsecond, reaches the open end at the oscillograph elements and steps the voltage up. This latter wave causes a reflection which in turn arrives in another 0.4 microsecond and steps the voltage up again, and so on. Thus the time between steps is the time it takes a wave to travel the full distance forward and full distance backward over the line. From the oscillogram, ten such step spaces were taken to increase the reading accuracy, and the recorded time was found to be 4.0 microseconds. The time for the ten step spaces corresponds to the time a wave would travel over 10×2×60 meters, or 1,200 meters, giving a velocity of $\frac{d}{t} = \frac{120{,}000 \text{ cm}}{4\times10^{-6} \text{ sec}}$, or in centimeters per second, 3.0×10^{10}, which is the velocity of light. The accuracy of the oscillographic determination was within one per cent, and thus it can be concluded that for the concentric-pipe assembly the time lags may be taken directly in terms of the line length and the velocity of light.

Determination of the Accuracy of the Time-Lag Measurement Method

The simplest checking test is to short-circuit *g* (figure 5*c*) so there is no time lag between the surge waves *S* and *T*. By introducing additional sections of transmission line with a plug system at the top of the transmission-line assembly of figure 4 it is possible to shift the electrical zero point. The introduction of additional sections on the positive-surge *S* side corresponds to artificial time lags and gives correct indications in every case over the entire range of the transmission-line assembly.

To check exact time-lag resolution conveniently, a trombone telescoping transmission line section was built up so that the timing wave could be shifted in fractions of the 10^{-8} range of the larger sections. It was found that a shift of the trombone section pictured in figure 7 corresponding to less than 10^{-9} second from the electrical zero would be sufficient to determine the tripping of the surge-recording unit involved. The possible resolving power in the measurement of time lags is, therefore, determined as at least as low as 10^{-9} second.

It is of importance to consider the exact relation between the number of transmission-line sections and the corresponding time of wave travel. The internal construction of the concentric-pipe transmission line may be seen in the trombone section of figure 7. The connecting-plug bends are designed with shielding covers to retain closely the same impedance characteristics as the rest of the line, and except for the small lengths covered by the higher-dielectric supporting washers we may quite accurately assume a velocity of wave travel equal to that of light. The velocity in the line fragments inside the washers will, however, be less, but the correction is calculable and the slowing down effect and also a sloping effect is illustrated in figure 8, for an initial rectangular wave after passing various numbers of supporting washers. The distinct time of arrival of the waves on the line is seen to be definite to within fractions of 10^{-9} second.

It was considered very desirable to check some of these very short time effects experimentally, and accordingly a cathode-ray oscillograph was designed with particular attention to fast operation. The dual-wave method responded to variations of a fraction of 10^{-9} second and an oscillographic record of its highest resolution or of the calculated curves of figure 8 would require comparable recording speeds. The highest recording speed reached with the cathode-ray oscillograph in the laboratory to date is shown in the oscillogram of figure 9. This oscillogram shows traveling-wave reflections on a concentric transmission line only 75 centimeters in length, connected to the oscillograph plates at the open side and short-circuited through a gap sparking over at the charging end. While figure 8 could not yet be checked

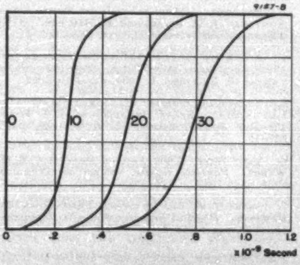

Figure 8. Calculated sloping and additional time lag of an initially rectangular wave as it passes 10, 20, and 30 supporting rubber washers of the concentric transmission line

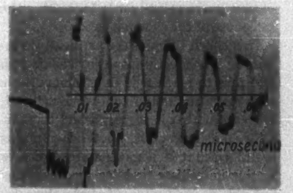

Figure 9. Fastest recording obtained on the oscillograph showing the short-circuit oscillations on a transmission-line section 75 centimeters long which are, even for so short a length, of definite traveling-wave type

directly since fractions of 10^{-9} second would scarcely be discernible, yet it is apparent that the oscillations are very definitely of a traveling-wave character even for such a short line length, and there is surprisingly little damping with most of that present largely attributable to the resistance of the shorting gap.

It is hoped to build the artificial transmission line directly into the oscillograph and thus to reach records of comparable time resolution to the dual-wave method, but even if that is accomplished successfully the dual-wave method remains useful, since it is so much more direct in getting immediate time-lag records without the necessity for photographic development.

Importance of Gas in Electrodes for the Glow-to-Arc Transition

F. A. MAXFIELD
MEMBER AIEE

H. R. HEGBAR
ENROLLED STUDENT AIEE

J. R. EATON
MEMBER AIEE

IN an earlier work[1] on the probability of glow-to-arc transitions in a low-pressure mercury-vapor discharge it was pointed out that these transitions occur in a completely random fashion and that the probability of a transition increases with an increase of pressure, cathode-current density, or glow voltage. In particular, cathode temperature was found to be very important, the transition probability being several times higher in a narrow temperature range near 425 degrees centigrade than it is at either lower or higher temperatures. The possible causes of these transitions were also investigated and the only explanation that seemed consistent with the experimental results obtained was that each transition was due to a burst of gas from the electrode surface. It was felt that even if the amount of gas given off in each burst was very small, the random appearance of these bursts from various parts of the electrode surface could explain the experimental results obtained.

This paper deals with further studies of an unstable glow discharge in mercury vapor which lend support to the theory that the causes initiating glow-to-arc transitions* are probably small bursts of gas nonuniformly emitted from the electrode surface. The experimental studies show that the transition probability continually decreases when the electrode is kept hot and bombarded with positive ions over a period of several days, but when the electrode is allowed to remain cold, even overnight, the transition probability is greatly increased. Two quite different curves of transition probability as a function of oil-bath temperature can be obtained, depending upon the glow current used. With glow current densities of about 1 milliampere per square centimeter the probability of a transition increases with oil-bath temperature but with very low values of glow current (0.025 milliampere per square centimeter) the probability of a transition decreases with an increase of oil-bath temperature. Additional support for the theory has been found in an examination of many experiments by other investigators. In all of these, we find that it is easy to explain the results obtained if we admit the possibility of gas bursts occurring on the electrode surface. That the amount of gas emitted in the form of a burst can be very small is substantiated by some calculations which show that the conditions necessary for the formation of a cathode spot are fulfilled by the emission of as few as 10^{11} atoms. This is a much smaller amount of gas than can be detected by ordinary means. Finally, the results indicate that the complete elimination of this cause for the glow-to-arc transition is very unlikely since a complete outgassing of the electrodes is impossible in any vapor tube.

Experimental Results

The experimental tube used for these tests is shown in figure 1. In this figure, *T* is the electrode used for the cathode of the glow discharge. *A* is the anode of the arc discharge used to furnish ionization for the unstable glow discharge, and *K* is the anode used for the keep-alive arc. No mercury is shown in the tube but in operation enough mercury was used in the cathode pool to bring the level up to the tungsten spot fixer, *F*. In operation a high negative voltage—the glow voltage—was applied to the test electrode, *T*. The positive-ion current collected by this electrode we shall call the glow current. Under normal conditions this current was relatively small, amounting to a few milliamperes per square centimeter of electrode area at the most. Under some conditions, however, the form of the discharge would change spontaneously from the normal high-voltage low-current type to a high-current low-voltage discharge and a cathode spot would appear on the electrode surface. With the circuit arrangement used (see figure 2) this low-voltage discharge could not be maintained. Thus the cathode spot was soon lost and the glow (that is, high voltage) discharge re-established. The average

* When we speak of a glow-to-arc transition we will always mean those spontaneous transitions that cannot be explained as due to external causes or causes which, under special conditions, can be removed. For example, we are excluding such causes as mercury drops hitting the cathode, or patches of impurity on the electrode surface, or breakdown to sputtered layers on insulators, etc. (See reference 1.) Glow-to-arc transitions, when encountered in mercury-arc rectifiers, are commonly called backfires.

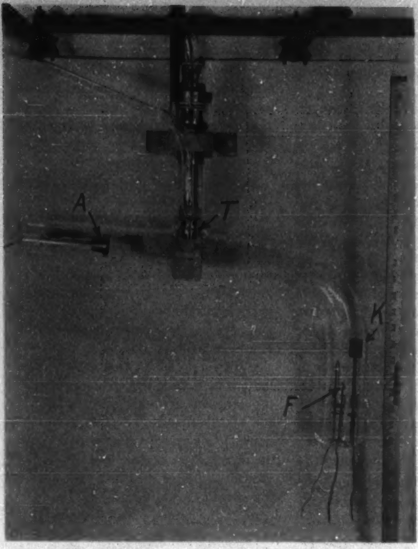

Figure 1. The experimental tube

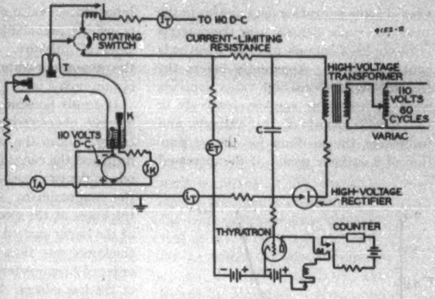

Figure 2. Circuit diagram

number of these glow-to-arc transitions occurring per second was measured by means of a counter and in the curves that follow it is this frequency that is called η. We see then that under the conditions of the test, η is a measure of the probability of a glow-to-arc transition.

Figure 3, curve 1, illustrates the important effect of gas in the high-voltage electrode on the transition probability. Throughout this test (with the exception of short intervals as noted below) electrode *T* was kept at 500 degrees centigrade by periodically using it as an anode of an arc discharge and the mercury-vapor pressure was kept constant by maintaining the oil-bath temperature at 51 degrees centigrade. For eight or ten hours each day the test electrode was bombarded by positive ions between the heating intervals. When this was done, the transition probability continually decreased. At the end of three days the heating and bombardment was stopped and the electrode was allowed to cool for 36 hours. It was then found that the transition probability under the same conditions of test had increased to the values observed on the first day.

It seems obvious from this test that, during the period when the test electrode was kept hot, gas was being continually emitted from the graphite test electrode under the combined action of heat and positive-ion bombardment. The emission of this gas in the form of small bursts results in the observed glow-to-arc transitions. When the electrode is allowed to cool, even though the tube remains evacuated, the electrode absorbs gas, mercury vapor probably, which is not emitted until the electrode is again heated and bombarded with positive ions.

A further indication of this effect is given by curve 2. The data for this were taken concurrently with the data for curve 1. The data for curve 2, however, were obtained by measuring the transition probability during the 10 or 15 minutes immediately after all arcs were extinguished in the tube. Obviously under these conditions the electrode could not be kept hot, but the cooling was only allowed to continue for the period of the test. This affected the results somewhat as the points at two days indicate. The average transition probability for the whole 12 minutes of the test is seen to be slightly higher than for the last 10 minutes. Although the ordinates are not the same, the similarity of the two curves is very striking. Here again it seems that the continued positive-ion bombardment and heating decreases the gas emission and the probability of the formation of gas bursts.

It seems hardly necessary to add that all the tests were performed on an electrode and with a tube that would ordinarily be classed as "thoroughly" treated. There was no visible increase in pressure during operation. The foreign gas pressure was less than 0.02 micron in all tests and the electrode had undergone a long period (more than $2^1/_2$ weeks) of heating and positive-ion bombardment before these tests were started.

This decrease in transition probability with heating and positive-ion bombardment is strikingly shown in some further tests made with no arcs in the tube. Figure 4 shows the results obtained. After the tube had been standing for some time at room temperature (that is, overnight), the curve marked 1 was obtained as the oil bath temperature was raised to 60 degrees centigrade. The electrode was then heated and bombarded with high-energy positive ions for about 72 hours. After this treatment another test of transition probability was made with all arcs out in the tube and it was found that, regardless of the oil-bath temperature, the transition probability was practically zero. This seems to show that

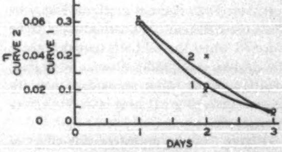

Figure 3. Effect of treating time on transition probability

Oil-bath temperature 51 degrees centigrade; temperature of electrode 500 degrees centigrade; $E_T = 15{,}000$ volts

Curve 1—$I_K = 11.5$ amperes; $I_A = 0$

Curve 2—$I_A = 0$ $I_K = 0$

even if some ionization does appear in the tube, the vapor density near the cathode is rarely high enough to cause a cathode spot to appear. Apparently before the treating process local high vapor densities were occurring at random intervals in the neighborhood of the cathode and furnishing the medium for the production of a cathode spot. If the increased transition probability is due to bursts of gas, we can easily see that an increase in the oil-bath temperature will, by increasing the vapor pressure in the tube, increase the relative importance of any small burst of gas from the electrode. In other words, a burst of gas which may not be large enough to initiate the formation of a cathode spot when the oil-bath temperature is 30 degrees centigrade may be entirely sufficient for a cathode spot to be formed when the oil-bath temperature is 60 degrees centigrade, since at 60 degrees centigrade the vapor pressure of mercury is ten times as great as it is at 30 degrees centigrade.

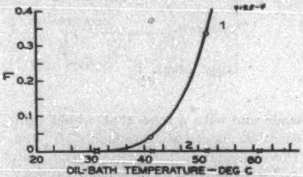

Figure 4. Effect of pressure on cold breakdown before and after treating

Figure 5 shows an interesting effect of pressure on the transition probability when there is sufficient ionization present from auxiliary arcs to have a space-charge sheath. Curve 2 in this figure is similar to the curves in the previous paper showing the dependence of transition probability on gas pressure. Curve 1 taken at a slightly higher voltage and drawn to a larger scale shows the effect of greatly reducing the current density. The striking difference between the curves is evident. With current densities of the order of 1 milliampere per square centimeter the transition probability increases with pressure but with a current density of 0.025 milliampere per square centimeter the transition probability actually decreases as the mercury-vapor pressure is raised. It would seem that at some intermediate value of current density the transition probability would be independent of pressure. Unfortunately with the present apparatus it was impossible to obtain such a test.

It seems possible to explain these divergent characteristics at least qualitatively. From the values of the voltage drop and the current density at the cathode in the two cases it is easy to calculate the approximate space-charge sheath thickness at the electrode.[2] In the case of the larger current (curve 2) the sheath thickness was thus found to be of the order of 2 centimeters, whereas in the case of the low current density (curve 1) the calculation gives a sheath thickness of 16 centimeters. The mean free paths of the mercury ions varied (in both cases) between approximately 1.4 centimeters at 30 degrees centigrade to approximately 0.17 centimeter at 60 degrees centigrade. Because the mean free path is not large compared to the sheath thickness, the positive ions will lose a certain amount of energy in crossing either sheath. In the case of the 2-centimeter sheath the average number of collisions will vary between one and ten and the energy of the positive ion on striking the cathode will be practically the maximum value attainable in falling through the cathode dark space. In this case as the pressure is increased the decrease in energy of the positive ions when they strike the cathode will be slight. The upper curve in figure 6 might thus be a representation of the positive-ion energy at the cathode surface.

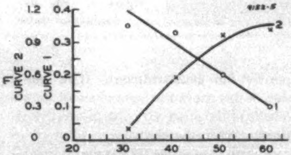

Figure 5. Effect of pressure on transition probability

Temperature of electrode 500 degrees centigrade

Curve 1:
$E_T = 15{,}000$ volts
$J = 0.0268$ milliampere, per square centimeter
Curve 2:
$E_T = 10{,}500$ volts
$J = 1.007$ milliampere per square centimeter

If, however, the sheath thickness is large (16 or 20 centimeters) the positive ions will make many collisions in crossing the sheath; in fact, about ten times as many as with the 2-centimeter sheath. The total loss in energy—assuming the same loss in energy at each collision—will thus be ten times as great as with the narrow sheath and the energy of the positive ion when it strikes the surface could be represented as in the curve marked $S = 16$ centimeters in figure 6.

Changes in pressure can thus influence the transition probability in two ways. With an increase in pressure and the corresponding increase in vapor density the effect of a small burst of gas is much more pronounced and a cathode spot develops much more easily because of the increased vapor available for current conduction and amplification by ionization by collision. However, with an increase in vapor density the energy of the positive ions striking the cathode is reduced and the number of secondary electrons produced in the neighborhood of a burst is also reduced, reducing the chance that a self-maintaining discharge will be established. We can easily see then that with the narrow sheath (2 centimeters) the loss in energy of the positive ions with increased pressure will be slight and an increase in the transition probability will be observed because of the increase of the vapor density. When the sheath is thick (16 or 20 centimeters), however, the loss in energy of the positive ions is large (each ion making about 100 collisions in crossing the sheath at the highest pressure) and even though the vapor density increases the transition probability decreases because of the reduction in energy of the positive ions at the cathode and the corresponding decrease in secondary electron emission.

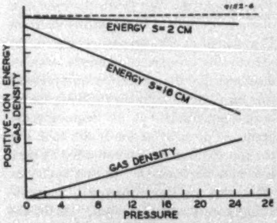

Figure 6. Effect of pressure on energy of incident positive ions

Other Evidence

Although the experimental results seem conclusive in themselves, it seems worth while to go further and determine what other evidence there is substantiating this theory of the glow-to-arc-transition. One is immediately struck with the fact that in any work involving a high degree of vacuum or relatively gas-free surfaces prolonged treating is always necessary. The usual process is to heat the electrodes and walls of the container to drive out as much gas as possible and then bombard them with electrons or positive ions to clean up still more of the gas. Anyone who has worked with high-vacuum apparatus is familiar with this procedure and it seems unnecessary to point out specific references.

Even though a high-voltage discharge is very useful in outgassing an electrode it is not completely successful, since the procedure is very slow and often introduces other complications. For example, any prolonged high-voltage treatment results in a very large amount of sputtering or electrode disintegration. Even with graphite electrodes, which probably exhibit as little sputtering as any, the tube is blackened in a relatively short time if a high-voltage discharge is used. In addition to this, it is well known[3,4] that when a discharge passes through a gas at reduced pressure there is a "cleaning up" effect present which tends to reduce the pressure in the vessel. The amount of "clean up" observed simply by the action of the discharge in trapping the gas on the electrodes or walls may sometimes be very pronounced resulting in a pressure drop from a centimeter or more to a fraction of a millimeter. In general, it has been observed that the materials which sputter most easily are those which make possible the most rapid clean up of residual gas. As far as high-vacuum work is concerned this is probably a very fortunate relation. Thus one of the most useful means of purifying a gas at low pressure is through the use of the so-called "Misch-metal" discharge which employs an easily vaporized and easily oxidized cathode material. On the other hand, graphite is about the best material to use for high-vacuum work when a clean, relatively unsputtered, tube is desired.

Solids in contact with a gas always have a layer of gas on their surfaces. This gas is only partly removed by heating and positive ion or electron bombardment. There is considerable evidence[3] that this gas is held on the surface in the form of complex and unstable compounds having formulas like $A_xB_yC_z$ where x, y, and z may have any value whatever. In the presence of the electric discharge, these compounds or combinations of elements may be continually forming and disintegrating. Whether complex compounds are formed or not, there is every reason to believe that there is a continuous process of adsorption and re-emission of gas going on at all times in the discharge.[5] Under some circumstances this adsorption and re-emission may proceed slowly and produce no perceptible change in the discharge tube and under other circumstances it may produce quite violent changes in the conditions in the tube.

A very striking experiment illustrating this effect was performed at the Westinghouse research laboratories a few years ago.* In this experiment a small U tube was constructed which had two mercury electrodes. Nitrogen was added until the pressure was about one centimeter. It was found, then, that when an arc was passed through the tube, the pressure rapidly decreased to less than a millimeter, but when the discharge was stopped and the electrodes were heated with a Bunsen burner, the gas was re-emitted in a very violent fashion, flashes of light and small explosions occurring on the mercury surfaces. This continued until the pressure returned to its original value. It is easy to see that if gas is held on the electrode in any such combinations as was apparently the case in this tube, gas bursts of sufficient size to initiate the discharge can easily occur.

The importance of unstable compounds in causing the formation of a cathode spot is illustrated by some work of Cobine[6] and Suits.[7] In studying the reignition characteristics of metallic arcs at pressures below 50 centimeters they found that oxides or impurities are necessary on the electrode surfaces if reignition is to occur. Essentially they were interested in determining the circumstances under which a cathode spot was or was not easily obtained on a negative electrode in a region of high ion density. Before arc reignition they had a nonself-maintaining glow discharge and when arc reignition occurred this discharge changed to a low-voltage arc. They found that impurities or oxides were necessary if arc reignition was to occur. Because they were working at relatively high pressures and with 60-cycle voltages they needed large gas bursts at frequent intervals to obtain arc reignition. In the absence of the impurities the nonself-maintaining glow discharge simply changed to a self-maintaining glow and no arc was formed.

Along this same line, some recent tests of H. Klemperer[8] show that it is possible to have breakdown and arc formation in low-pressure tubes at voltages much below those necessary for a stable glow discharge. He found that the voltage at which these arcs formed was extremely variable. These tests were very similar to the cold breakdown tests described in the preceding section and the variation in breakdown voltage which he obtained is probably due to the electrodes being treated differently in the various tests. The conclusion seems to be that gas bursts were occurring on his electrodes which caused the observed transitions. Because the tests were probably made over a period of many days with periods between during which the electrodes could take up gas, there is no reason why the results should be consistent. It has been found in the tests reported above that only when the electrode is maintained hot and the tests do not extend over too great a time is it possible to get consistent results.

Quite aside from the importance of adsorbed gas in causing cathode-spot formation, it is possible for this gas when emitted to influence other observations. For example, it is well known that untreated surfaces and surfaces with layers of oxide exhibit much greater secondary emission than well-cleaned surfaces.[9,10] This seems to substantiate the presence of gas bursts from the untreated surfaces. The true secondary emission from the untreated surfaces, in many cases, is probably no larger than from treated surfaces. It *seems* greater, however, because if bursts of gas appear, the secondary electrons will produce ionization by collision in the emitted gas and the current measured will be the secondary electrons *plus* the electrons formed by collision with neutral gas atoms.

A simple approximation of conditions in the positive-ion space-charge sheath near the cathode and the conditions necessary for the formation of a cathode spot can be made by assuming that the boundaries of a space charge sheath of thickness S are infinitely extended plane parallel surfaces and that the number of positive ions diffusing into the sheath per unit area per second is P_s.

If α is the average number of ionizing collisions made by an electron per unit distance and γ is the number of secondary electrons produced at the cathode by each incoming positive ion it is easy to obtain an expression for the current density in the form of equation 1.

$$J=qP_s\left[\frac{1+\gamma}{1-\gamma\left(e^{\int_0^s \alpha dx}-1\right)}\right] \qquad (1)$$

Here q is the charge on each ion and e is the base of the natural system of logarithms. This equation fits in very well with experiment, for from observations on the current collected by a negative electrode in a region of high ion density we know that the current is directly proportional to the number of ions diffusing into the sheath. We also know that the coefficient of secondary emission due to positive-ion bombardment increases approximately linearly with the energy of the positive ions when the energy is of the order of several thousand volts.[11] Independent experiments have shown[12] that the current collected by a negative electrode increases approximately linearly with the voltage and the dependence of J on γ and voltage is thus checked, at least qualitatively.

---

* We are indebted to Doctor J. Slepian for permission to mention this research.

The equation above also states that there are certain conditions under which we may have a self-maintaining discharge in the sheath at the cathode. The conditions are exactly the same as the conditions necessary for sparking to occur in gases at higher pressures[10,13], namely,

$$\gamma\left(e^{\int^{d}\alpha dx}-1\right)=1 \tag{2}$$

This equation, has two distinct interpretations. One is that if the pressure or voltage is varied until this equality is fulfilled a self-maintaining discharge will be established which will be a stable glow discharge utilizing the whole or a large part of the cathode surface. This condition is readily obtained in a discharge tube by raising the pressure to a high enough value (50 or 100 microns, for example).

A more important characteristic of equations 1 and 2 is that it is possible to see how a gas burst could initiate a glow-to-arc transition. Suppose a gas burst occurred over a very small area of the cathode surface. The vapor density would be increased near this local spot and the current density would increase greatly. It is conceivable that, in the region of the high vapor density, during the burst the condition for a self-maintaining discharge could be fulfilled, and since the area involved is small and the current density large a cathode spot may form. The discharge then would take the form of an arc rather than a glow discharge. We can see also that if the voltage drop across the sheath is increased, γ will be increased and it may be possible to initiate the transition with a smaller amount of gas in a burst. In this respect, the theory predicts the observed increase in transition probability with voltage. When the sheath is not too thick the observed increase of transition probability with pressure can also be predicted. As the pressure is raised, the amount of gas appearing in a burst or the size of a burst can be reduced and still the condition necessary for a self-maintaining discharge will be fulfilled. Since in our theory we have postulated that bursts of all sizes are probable, it is obvious that as smaller bursts become effective, the transition probability will increase.

Some estimates of the amount of gas necessary in a burst in order to provide for the initiation of a cathode spot can easily be made. For a 0.5-ampere arc the area of the cathode spot is about 10^{-5} or 10^{-4} square centimeters.[14] Thus, taking the larger of these values, if we assume that the voltage drop across the positive-ion space-charge sheath at the cathode of an arc is about 10 volts and that the field intensity at the surface of the cathode is of the order of 10^6 volts per centimeter (10^8 volts per meter) and at the edge of the sheath is zero, we can estimate the charge density in the sheath. The equation

$$E=\frac{\rho d^2}{2p} \tag{3}$$

gives the voltage drop across a uniform space charge sheath when the electric intensity at one edge of the sheath is zero. Here ρ is the charge density, d is the thickness of the sheath, and p is the permittivity of free space. If $d=E/F_{\max}$ where F is the electric intensity, d will have a value in this case of about 10^{-7} meters. Solving equation 3 for ρ and multiplying by the area (10^{-8} square meters) and the thickness (10^{-7} meters) of the sheath, the total charge contained in the sheath is found to be about 1.77×10^{-11} coulombs. This corresponds to about 10^8 singly charged positive ions. There is evidence[15] supporting the view that at the cathode spot of an arc the gas is essentially 100 per cent ionized. If this is the case, then the emission of 10^8 molecules of gas would be sufficient to permit the formation of a cathode spot. This amount of gas is equivalent to a mass of mercury vapor of 3×10^{-14} gms. At atmospheric pressure it would represent a volume of 4×10^{-12} cubic centimeters and in a vessel of one liter volume it would raise the pressure by only 3×10^{-12} millimeters of mercury. We see then that this amount of gas is much too small to be detected by any ordinary means. Volumes of gas 1,000 or 10,000 times as large would still be undetectable.

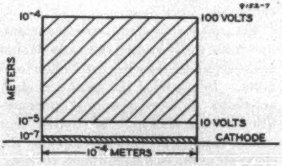

Figure 7. Conditions in the neighborhood of a gas burst

Referring now to figure 7, if we assume that the burst of gas consisted of as much as $10^3\times10^8$ or 10^{11} molecules and that before the cathode spot formed it had spread out so that it covered an area of 10^{-8} square meters to a depth of 10^{-4} meters, the gas density would be increased in this volume from about 10^{20} molecules per cubic meter to 10^{23} molecules per cubic meter. This increase in density would reduce the mean free path of the secondary electrons from about 10^{-2} meters to about 10^{-5} meters. In the glow with 10,000 volts across a two-centimeter sheath the maximum field intensity at the cathode would be approximately 10^6 volts per meter. Thus by the time an electron had fallen through a distance of 10^{-5} meters (one free path) it would have acquired an energy of 10 volts and in the distance from 10^{-5} to 10^{-4} meters from the cathode it will produce most of its ionization. Obviously with the building up of space charges the secondary electrons will gain sufficient energy for ionization in shorter distances and the ion density will increase near the cathode, as it should if a cathode spot is to be formed.

The question now arises of whether or not the gas will remain in the neighborhood of the cathode long enough for a cathode spot to form. Loeb[16] in discussing the breakdown of spark gaps says that the observed values of time lag of breakdown are so short (10^{-7} to 10^{-8} seconds) that neither positive ions nor electrons could possibly have crossed the gap in the intervals used. Because of this it was necessary for him to postulate other mechanisms for building up space charges, or current densities in very short times. One of these is photoelectric emission of electrons at the cathode due to the resonance collisions that the secondary electrons make in moving away from the cathode. Other explanations are the formation of large space charges in short distances by the action of "electron avalanches" or by the increase in α/p with F/p. Here F and α have the same meaning as in the discussion above, but p now is the gas pressure. Regardless of the mechanism, the physical processes involved in the breakdown of a spark gap and in the transition from a glow to arc are essentially the same. In either case we start with a small amount of ionization and through some ionizing process establish a self-maintaining discharge.

When considering the glow-to-arc transition we realize that the distance involved in the establishment of a self-maintaining discharge is much less and consequently it becomes easier to explain the rapid increase in ionization. It is even possible for ionization by collision alone to account for the large space charge necessary for the cathode spot of an arc. If we assume that the field intensity at the cathode in the glow is 10^6 volts per meter and that the electrons move with constant acceleration, it will only take 10^{-11} seconds for the electron to travel 10^{-5} meters and less than 10^{-8} seconds for the positive ions to travel the same distance. This is a time interval smaller or at least of the same order of magnitude as that required for the breakdown of a spark gap. Thus we could attribute the increase in ionization necessary for cathode-spot formation simply to ionization by collision.

Up to now we have been tacitly assuming that the high gas density would remain in the neighborhood of the cathode long enough for a cathode spot to form. To estimate the speed with which the emitted gas molecules would move away from the cathode, we can assume that the gas is emitted with the temperature of the electrode (500 degrees centigrade) and moves away from the electrode with the gas molecules making no collisions. This should give an upper limit for the velocity of the gas particles. On this assumption we calculate an average velocity of about 1,000 meters per second. This would mean that it would take at least 10^{-7} seconds for the gas to move 10^{-4} meters. This also is a time of the same order of magnitude as that required for spark-gap breakdown. Certainly then if a gas burst occurs, the gas will not diffuse away too rapidly for a cathode spot to form.

Conclusions

Any analysis of the results presented here seems to substantiate the theory that the glow-to-arc transition is caused by the emission of gas from the electrode surface in the form of small bursts. The continual decrease in transition probability as long as the cathode is being heated and bombarded with positive ions and the increase in transition probability when this process is stopped can only indicate that gas is being absorbed or adsorbed at the electrode surface during periods when the tube is cold and is reemitted when the electrode is heated and bombarded with positive ions.

That this gas is the most important factor also seems evident, for in order to have a cathode spot form we must provide a medium in which a very rapid increase in ion density can occur. We conclude that this gas must be given off in the form of small bursts appearing at random intervals on the electrode surface, for only thus can we explain the dependence on glow current and voltage, pressure, electrode temperature, and time.

After reviewing all the evidence, the conclusion seems obvious. Without a doubt, the results obtained in this laboratory have done more than point out again the large effect that gas trapped in or on electrodes can have in influencing experimental results. This has been known for a long time. What the experiments here have shown is that it is practically impossible to degas electrodes as long as any gas or vapor such as mercury is allowed to remain in the tube. In a mercury-vapor tube the electrodes are probably continuously adsorbing and reemitting a certain amount of the gas. All the evidence seems to point to the fact that this gas is not emitted uniformly over the electrode surface but instead is emitted in very small bursts. The gas contained in the burst may represent only 10^8 or 10^{11} molecules yet this amount is still sufficient, as shown by the calculations above, to initiate a cathode spot if the burst occurs on a negative electrode. Finally, the results indicate that the likelihood of ever being able completely and permanently to outgas an electrode in a mercury-vapor tube is very remote.

Lightning Investigation on a 220-Kv System—III

EDGAR BELL
MEMBER AIEE

Synopsis: This paper briefly describes surge-crest-ammeter measurements of lightning strokes and structure network currents, and summarizes transmission-line experience with and without overhead ground wires, buried-cable grounding networks, expulsion protective gaps, station-type lightning arresters, and spillway gaps.

LIGHTNING research has been conducted for the past 13 years[1–6] by the Pennsylvania Power and Light Company, the General Electric Company, and the Ebasco Services, Inc., chiefly upon that portion of the Pennsylvania-New Jersey 220-kv interconnection circuit between Wallenpaupack and Siegfried, Pa. This 65-mile-long circuit is of aluminum-conductor steel-reinforced three-conductor horizontal-configuration steel-tower construction, having originally 14-unit insulation. Since 1932 the 28-mile section from Wallenpaupack to Bushkill has been called the Wallenpaupack tap, and the remainder constitutes part of the Siegfried-Roseland line.

The original line was without overhead ground wires. Because reference 6 ably describes the construction and the historical background leading to the various improvements made from time to time, this paper will merely enumerate them briefly in table I.

Records of insulator flashovers, line tripouts, magnetic oscillograms, and surge indicators[4] have been kept regularly. By these means it was frequently possible to not only estimate[7] approximate locations of faults but to determine actual towers and assemblies flashed during specific tripouts. When available, surge-crest-ammeter[8] records were of much assistance.

Of various measuring devices used from time to time, such as surge-voltage recorders, lightning-stroke recorders, storm-severity meters, cathode-ray oscillographs, field-intensity recorders, etc. none are now used except surge crest ammeters. During 1936, 1937, and 1938 these were used as follows:

1936. One corner leg on about half of the 314 structures, all four corner legs on remaining structures including *SR* 8–1 to 10–1 (expulsion gaps); lightning rods and overhead ground wires at 5 towers *WT* 12–2 to 12–6; lightning rods at 5 towers *SR* 23–2 to 24–1; one 50-foot crowfoot on 46 towers *WT* 6–5 to 18–4 (at mid-point or 25 feet from tower); 18 long 250-foot crowfeet (at points 25, 125, and 225 feet from tower); on High Knob continuous counterpoise *WT* 11–4 to 14–1 (at points 3, 100, 200, and 300 feet from tower); and on Wallenpaupack Thyrite arresters (*Y* and *W* phases).

Table I. Locations of, and Time of Installation of Construction Additions to Wallenpaupack Tap and Siegfried-Bushkill Section of Siegfried-Roseland Line

	Name	Location	Length in Miles	Year
1.	Conventional overhead ground wires	Siegfried to *SR* 5–3	4.6	1927
2.	Conventional overhead ground wires	Wallenpaupack to *WT* 20–2	19.4	1927
3.	Continuous counterpoise (High Knob)	*WT* 11–4 to 14–1	2.6	1929
4.	Two more insulator units on outside insulator assemblies	Wallenpaupack to *SR* 24–5	40.0	1929
5.		*SR* 24–4 to 21–5	4.0	1930
6.	Diverting cables (overhead ground wires)	*WT* 22–1 to 25–4	3.8	1930
7.	Special crowfoot cables	*WT* 22–1 to 25–4	3.8	1930
8.	Short crowfoot cables	Wallenpaupack to *WT* 20–2	16.8*	1930
9.	Surge (flashover) indicators	Entire line	65.0	1930
10.	Short crowfoot cables	Siegfried to *SR* 5–3	4.6	1931
11.	Thyrite lightning arresters	Wallenpaupack *Y* and *W* phases		1934
12.	Ten expulsion gaps, *W* phase	*SR* 8–1 to 10–1	2.2	1935
13.	200-foot extensions to crowfeet	24 towers of item 8		1936
14.	Continuous counterpoise	*SR* 5–3 to 17–4	12.5**	1937
15.	Ten expulsion gaps, *Y* phase	*SR* 8–1 to 10–1	2.2	1938

* Does not include 2.6-mile section of item 3.

** Nonoverhead-ground-wire section of line, includes items 12 and 15.

1937. Four corner leg brackets at 10 towers *SR* 8–1 to 10–1 and 21 other scattered towers as well as 51 towers *WT* 6–5 to 19–5; on structure diagonal braces at 15 towers *WT* 10–1 to 10–5, 12–2 to 12–6 and 14–2 to 15–1; overhead ground wires at these towers; lightning rods and long crowfeet same as 1936 except that latter were extended to *WT* 19–5 (3 more towers) and inner installation moved from 25 to 3 feet from tower; short crowfeet same as 1936 except they were extended to 19–5 (2 more towers) and installations were moved to or made on all crowfeet at distance of 3 feet from tower; High Knob counterpoise and Wallenpaupack arresters same as 1936.

1938. Two corner legs on 50 towers *SR* 5–3 to 17–4 (new continuous counterpoise); four corner legs on 10 towers *SR* 8–1 to 10–1 (expulsion gaps) and 28 towers *WT* 10–1 to 15–1; overhead ground wires and structure diagonal braces at these latter 28 towers; High Knob counterpoise at distances of 3 feet only from towers; long and short crowfeet same as 1937 but only at 14 towers *WT* 10–1 to 15–1; lightning rods at *WT* 12–2 to 12–6 only; and Wallenpaupack arresters same as 1936 and 1937.

Results

MAGNITUDES OF STRUCTURE CURRENTS

During 1936 to 1938 some data permit evaluation of structure current magnitudes, and which are assumed to be the sum of currents in all 12 structure members directly connected to tower footings. These members are the four corner legs and eight diagonal braces. Within four or five feet of the ground these members are interconnected by others. Measurements were made before interconnection occurred, and magnetic links were so located that they were not appreciably affected by current in any member except the one to which they were coupled.

Table II lists data where all three measurements (leg and connected diagonals) exceeded traces. Ratios (of total current over corner-leg current) range from 1.64 to 2.75 but a tentative figure of 2 has been selected for general use in correcting records of leg current only.

MAGNITUDES AND FREQUENCY OF OCCURRENCE OF LIGHTNING STRUCTURE CURRENTS

Figure 1 shows frequency of occurrence of lightning structure currents of various magnitudes. Only 9 per cent of the total records exceeded 50,000 amperes and less than 1 per cent exceeded 100,000 amperes. The polarities of these 370 records were

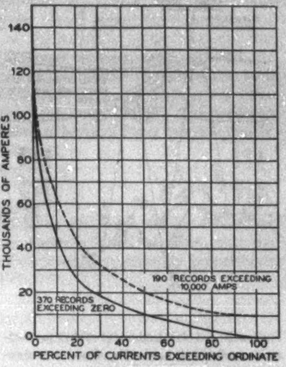

Figure 1. Numbers and magnitudes of structure currents caused by lightning

negative 96 per cent, positive 3 per cent, and uncertain 1 per cent.

The structure currents represented by figure 1 are twice the sums of corner-leg currents, to allow for the generally unmeasured currents in the structure cross bracing. Somewhat similar curves[9,10,11] have been previously published. Those entitled "Tower Currents" are of corner-leg currents only. Others entitled "Stroke Currents" are summations of corner-leg currents from two or more adjacent structures.

It will be shown later that measurements in overhead ground wires or lightning rods are necessary for proper determination of stroke currents, and that summations of structure currents only from adjacent towers can at least in individual cases, sometimes lead to erroneous conclusions.

Numbers and Current Magnitudes of Lightning Strokes to Overhead Ground Wires and Structures

It is impracticable to present all of the 1936–1938 records from which stroke locations and/or magnitudes were satisfactorily determined. These were obtained from short sections of line ranging from 2.6 miles in 1936 to 5.2 miles in 1938 and showed that at least 23 well-defined strokes occurred, 6 to structures and 17 to spans. On this basis and for this line, it can be assumed that 75 per cent of the strokes occur to overhead ground wire spans. Some 400 German[12] records from lines of generally lower voltage ratings and greater numbers of structures per mile show ratios ranging from 51 to 64 per cent each year. A few Japanese[13] records indicated 95 per cent.

Figures 2, 3, and 4 are typical records from strokes to overhead ground wires. Figure 6 is typical of lightning-rod stroke

Figures 3 and 4. Lightning strokes to mid-span overhead ground wire, showing respectively non-typical deficiency current and typical excess current

records. Figure 5 is presented to show how two nearby strokes can cause records to be complicated and only partially intelligible.

In general, the sum of upward-flowing structure currents and in-flowing overhead-ground-wire currents exceed by some 20 to 35 per cent the stroke current as measured in lightning rods or stricken overhead wires. Figure 3 is an exception, and shows a 26 per cent deficiency instead of an excess. The reason for apparent current differences at junction points is probably associated with the facts that magnetic-link records are of maximum or crest currents instead of instantaneous values, and that surge-current changes may occur at impedance junctions.

Five lightning-rod records were 33,000, 33,000, 38,000, 57,000 and 62,000 amperes. Six well-defined mid-span strokes were 22,300, 32,950, 42,050, 45,000, 62,500, and 70,500 amperes. The average for each group is nearly 45,000 amperes.

* Double leg current measurement.

Many surge-crest-ammeter records are quite small, registering only as traces on the indicating meter. Interpretation of small records has been to classify those less than 10 on the indicating meter as traces, and to assign nominal values to them. For counterpoise, crowfeet, and tower diagonal brackets, traces have been marked 500 amperes. For lightning rod,

Figures 5 and 6. Lightning strokes to lightning rod. Figure 5 is complicated by an adjacent stroke. Figure 6 is a single record showing typical excess current

overhead ground wire, and tower leg brackets, traces have been marked 1,000 amperes.

It is already apparent that the most satisfactory method of determining locations of transmission-line lightning strokes is from measurements in lightning rods and overhead ground wires. Stroke magnitudes are also most accurately measured by these means. Table III presents data from nine adjacent structures caused by three separate and distinct strokes. It shows that structure currents alone give an incomplete picture and may lead to erroneous conclusions as to stroke locations, magnitudes and numbers.

Table IV. Currents in Towers, Crowfeet, and Footings

Tower Number	Leg Number	Current: Leg	Diagonals		Sum	250-Foot Crowfeet	Footing*	Per Cent of Current Supplied by Crowfoot	See Figure

CURRENTS IN CONTINUOUS COUNTERPOISE ON OVERHEAD-GROUND-WIRE LINE

Figure 2 of reference 5 shows typical and detailed counterpoise records. Figures 5 and 6 herein show a few more. A single stroke may affect a mile or more of cable. Currents entering a span are less than those leaving the preceding span because of current diverted up the structure. Currents leaving a span are greater than those entering because of current collected in that span.

This 2.6-mile-long counterpoise has effectively prevented flashovers since its installation early during 1929. During the $1^1/_2$ preceding years while overhead ground wires alone were in use, at least two towers were flashed. The only published oscillogram[9] of a lightning surge obtained at the point of stroke contact showed a wave front of 5–6 microseconds. If such value is typical the effectiveness of 1,000-foot-span continuous counterpoise can be explained by the multi-velocity wave theory.[14]

CURRENTS IN NONCONTINUOUS COUNTERPOISE, OR CROWFEET

Figures 2, 3, and 4 show the two types of crowfeet in use. Most installations consist of four 50-foot cables at right angles to each other and 45 degrees to the direction of the line. A total of 118 overhead-ground-wire structures were so equipped during 1930 and 1931. During 1936, at 24 of the *WT* structures having the highest resistances, a 200-foot extension parallel to the direction of line was made on one crowfoot.

Table IV lists 12 sets of records in which the corner leg and diagonal member currents all exceeded traces. These records show the currents in tower corners and crowfeet. Tower-footing currents are computed on the assumption that they are the arithmetical difference between currents in structures and crowfeet. This assumption is not strictly correct but is the best that can be done lacking knowledge of time-current surge characteristics.

These data indicate that for 50-foot crowfeet about 37–47 per cent of the tower current is supplied by such cables, and the remainder by the footings. For the longer crowfeet, indicated ratios are erratic, due possibly to the fact that such cables may lie partly in loose dry rock, firm soil, and swamp. The tendency seems to be for the long cables to supply about 76 per cent of the tower corner current as contrasted with about 43 per cent for short cables. It should not be assumed that 250-foot cables are only 76/43 as efficient as 50-foot cables; on the contrary it will be shown that the efficiency is approximately proportional to length.

In the case of 250-foot cables, current measurements were made at distances of 125 and 225 feet from the tower. During 1936 measurements were also made at a distance of 25 feet, but during 1937 and 1938 this distance was changed to 3 feet. A total of 47 sets of records was obtained, but only 14 of these were sufficiently large so that all three exceeded traces. Table V lists these and also measurements from 50-foot crowfeet at the same towers.

Items 8–11 and 13–14 indicate that the ratio of currents 3 feet from the tower, in long and short crowfeet, vary from 2.4 to 6.9. Averaging the 18 records from short cables and the corresponding six from long ones shows the ratio of currents to be 9307/1864 or 5.0. This is the same ratio as the cable lengths. We can conclude that the rate of collection of current is generally proportional to the length of installed cable, at least up to 250 feet.

From items 4–6, 8–11, and 13–14 of table V we can also determine relative rates of collection of current for the different sections of long cable. Percentages of current measured at 3 or 25 feet, 125 feet, and 225 feet from the tower average 100, 55, and 15.5. From these,

Table V. Currents Measured at Following Distances From Tower

Item	Year	Tower	250-Foot Crowfeet: 3 Ft	25 Ft	125 Ft	225 Ft	50-Foot Crowfeet: 25 Ft	3 Ft	3 Ft	3 Ft

Towers† having one long and three short crowfeet	1936–38	0	0.000

† Towers equipped with overhead ground wires.

* One two-phase and two three-phase flashovers.

** None of these flashovers was multiphase.

average rates of collection of current can be computed; these are respectively, 0.37, 0.395, and 0.62 per cent per foot for the near, middle, and distant sections. It is believed that at the extreme end of a cable rates as great as 5 may be reached. It may also be of interest that at none of the towers shown in tables IV or V or figures 2 to 6 did insulator flashover occur.

EFFECTIVENESS OF OVERHEAD GROUND WIRES AND BURIED COUNTERPOISE AND CROWFEET

The effectiveness can be judged from table VI which briefly summarizes flashed tower data.

EXPERIENCE DURING ONE SEASON ON $12^1/_2$-MILE SECTION OF SIEGFRIED-ROSELAND NONOVERHEAD-GROUND-WIRE LINE HAVING CONTINUOUS BURIED COUNTERPOISE

At least nine strokes or groups of strokes were measured although ten seem to have occurred. Currents were measured or indicated in 27 structures, and on 14 of these, plus 2 others, insulators were flashed. Four of the strokes occurred to the 2.2-mile section where expulsion protective gaps are in use. No flashovers or tripouts occurred and it is believed that the gaps avoided flashover in three cases. One apparent stroke was too small to measure, but it caused a single-phase flashover. The remaining five measured strokes or groups of strokes are tabulated in table VII.

Stroke number 5 is most unusual in a number of respects. It seems to have been a group of several strokes, two of which were quite large and of opposite polarity. Also, these two strokes either were highly oscillatory, or were multiple and consisted of opposite-polarity components. We cannot determine the actual stroke magnitudes, but two were apparently of the order of 100,000 amperes (summation of structure currents less 20–35 per cent). Had records all been of negative polarity, the summation would have been 236,000 amperes, and there would seem to be some justification for such addition since the larger currents were in the two middle towers. It has previously been shown that such summations can be misleading.

These strokes occurred on December 10, 1938. A magnetic oscillogram shows all three phases faulted at the very beginning of the record. One vibrator has a six-cycle acoustic time delay; its record shows about one cycle of residual current, indicating that all phases were not faulted simultaneously.

A tentative conclusion is that during 1938 the counterpoise performed about as well as expected. From records available in 1937 from overhead ground-wire sections of line, it was anticipated that about 25 per cent of strokes would contact structures, or a total of two or three strokes. At least one stroke so occurred, and perhaps several others, but in these cases the exposed conductors seem to have been struck as well. Possibly successive components of a multiple stroke involved a line conductor at some time, and the counterpoise was effective only in limiting the fault to such stricken conductor. The counterpoise can be effective in preventing tower flashover only in those cases where no stroke or side streamer contacts a line conductor.

EXPERIENCE WITH 220-KV EXPULSION PROTECTIVE GAPS

Late in 1935 gaps were installed on phase *W* (west 14-unit insulator assemblies at ten nonoverhead-ground-wire towers *SR* 8–1 to 10–1 inclusive. During the winter of 1936–37 two gaps were removed for manufacturer's inspection. In March 1937 while surge crest ammeters were not in use, a stroke destroyed two gaps. Shortly thereafter the previously removed gaps were replaced, and during

Table VII. Lightning Strokes to Line Having Continuous Counterpoise But no Overhead Ground Wires or Expulsion Gaps

Stroke Group Number	Tower Number	Estimated Structure Current*	Insulator Phases Flashed	Did Line Trip	Current in Second Loop	Remarks
1	16–5	−21,000	None	No		
2	13–1	− 5,500	W	Yes		Had counterpoise not been in use, strokes 2 and 4 would likely have caused three-phase faults similar to five multitower faults in the 12th and 13th miles during 1931 to 1937 inclusive
	13–2	− 9,500	W			
	13–3	−37,000	W			
	13–4	−10,000	W			
3	15–3	− 7,000	Y	Yes		
	15–4	−45,000	Y			
4	13–1	−17,500	W	Yes		
	13–2	− 8,500	W			
	13–3	+ & −?	W			
5	16–3	− 3,000	None	Yes		
	16–4	+ 5,500	None			For structures shown herein current measurements were made only in the two corner legs connected to the counterpoise. Currents shown are 2.67 times sum of leg measurements
	16–5	+ & −?	None			
	17–1	+40,000	W		−11,000	
	17–2	+81,000	X		−25,000	
	17–3	−78,000	YXW		+34,000	
	17–4	−37,000	X		+ 2,500	

* These values are 2.67 times sum of currents measured in the two legs which are connected to continuous counterpoise. This factor has been derived from the following tentative ratios of corner current to leg current: (*a*). Counterpoise legs 2.25. (*b*). Noncounterpoise legs 1.68.

Table VIII. Experience on Towers Partially Equipped With Expulsion Protective Gaps During 1936-38

Item	Flashed Towers	Period of Time	Number of Towers	Rate Per Mile Per Year
1	Nonoverhead-ground-wire towers (excluding 8–1 to 10–1)	1926–38	328	0.72
2	Total nonoverhead-ground-wire towers	1926–38	356	0.74
3	*SR* 8–1 to 10–1 only (13 years)	1926–38	28	0.98
4	*SR* 8–1 to 10–1 only (3 years) (flashovers on nongap-equipped assemblies)	1936–38	8	1.21
Towers Having				
5	Successful gap operations	1936–38	10–15*	1.5–2.3
6	Gaps destroyed	1936–38	2	0.30

* Actual minimum and probable total figures.

the rest of 1937 eight gaps were used. During 1938 the phase *W* replacement gaps and ten new gaps on phase *Y* (east) assemblies were installed.

Table VIII shows that lightning severity in the region traversed by these ten towers is greater than for the total nonoverhead-ground-wire sections of line. For example, items 1 and 3 show that the relative numbers of towers flashed was $1^1/_2$ times as great, and items 4 and 5 indicate that these ten towers were affected even more severely during the period when gaps have been used. Consequently, this short section of line has made an excellent proving ground for the gaps.

Item 4 involved eight towers and 11 assemblies, only two of which were equipped with gaps. During 1938 when all 20 outside insulator assemblies were gap equipped, at least two and probably six or perhaps seven gap operations occurred, but no insulators were flashed. Comparison of items 5 and 6 suggests that gap operations have been successful in from 83 to 88 per cent of the cases where they have been called upon to operate. This seems to be typical of experience with gaps of lower voltage rating, and represents fair protection.

THYRITE LIGHTNING-ARRESTER RECORDS, AND WALLENPAUPACK SPILLWAY-GAP FLASHOVERS

Since April 1934 two 16-unit Thyrite arresters have been in use on phases *Y* and *W* (outside conductors) at Wallenpaupack. At this location 42.5-inch ring-ring spillway gaps are in use on all three conductors. Table IX lists records which have been obtained.

It seems significant that no gap flashovers have occurred on the arrester-equipped phases and it can be concluded that the arresters are functioning satisfactorily.

Results and Conclusions

1. Most lightning strokes to this transmission line occur between negatively charged clouds and positive earth, and are termed "negative".

2. Approximately three out of every four strokes to an overhead-ground-wire section of this line occurred to such wires between structures. In no case did a measured stroke involve more than one of the two wires, nor cause insulator flashover.

3. Stroke-current magnitudes are believed to be most accurately measured by lightning-rod currents, or summations of currents in the two ends of stricken overhead ground wires. Twelve such strokes, all negative, have ranged in magnitude from about 20,000 to 70,000 amperes.

Table IX. Wallenpaupack Records From Thyrite Arresters and Spillway Gaps

Thyrite Arrester Records		Number of Spillway Gap Flashovers		
		Phases		
Phase, Polarity, and Amperes	Year	Y	X	W
	1926–1933	7	6	8
Y-650	1934	0	0	0
Y-240, *W*-440, *Y*-750	1935	0	0	0
Y-1600, *Y*-1600	1936	0	1	0
Y-3,700, *W*-1,500, *Y*-2,950, *W*-200	1937	0	1	0
None recorded	1938	0	0	0

4. Of 370 structure current records, 355 or 96 per cent were negative, 3 per cent were positive, and 1 per cent were uncertain. Of the 190 records exceeding 10,000 amperes, all but 4 were negative, as were the 3 records exceeding 100,000 amperes.

5. Structure currents are roughly twice as great as sums of corner-leg currents.

6. The practice of adding currents from adjacent structures is not recommended. It can give erroneous results for both numbers and apparent magnitudes of strokes.

7. Summations of total structure currents and in-flowing overhead-ground-wire currents are usually in excess of the lightning-rod current or out-flowing currents in the stricken conductor. Instantaneous surge-current changes are expected to occur at impedance junctions. Another factor is that current records are usually maximum or crest magnitudes, and not instantaneous values.

8. Buried counterpoise when used in conjunction with overhead ground wires provides multiple paths to ground for lightning, and distributes such current over long distances. Continuous counterpoise seems ideal, and a 2.6-mile section has had a perfect ten-year record. Noncontinuous or crowfoot cables have had an excellent but not quite perfect nine-year record in preventing insulator flashovers.

9. The effectiveness of overhead ground wires and efficient tower-footing grounding is concisely shown by the following:

Type of Construction	Towers Flashed Per Mile Per Year	Relative Effectiveness
No overhead ground wires	0.740	1.0
Overhead ground wires alone	0.200	3.7
Overhead ground wires and four short crowfeet	0.015	49.3
Overhead ground wires and continuous counterpoise	None	Infinity

10. The current (measured near the tower) in noncontinuous counterpoise seems to be in proportion to length of cable.

11. The rate of current collection for 250-foot crowfeet is nearly uniform for most of the cable but seems to increase rapidly near the free end.

12. Current measured near the tower in 50-foot crowfeet is about 43 per cent as much as in the three directly-connected structure members. For 250-foot cables this figure is 76 per cent.

13. Experience during one season with 12.5 miles of continuous counterpoise on nonoverhead ground wire is not conclusive because of incomplete measuring facilities. Performance seems to be as good as was expected. This includes:

(*a*). Avoidance of flashover for strokes to structures only, and

(*b*). Prevention of spread of flashover from stricken to nonstricken line conductors.

14. 220-kv expulsion protective gaps installed on one or two phases at ten towers are believed to have avoided tripouts in eight cases, and failed once. In the former cases the three largest structure currents, all from separate strokes, were 35,000, 26,000, and 22,000 amperes. In the latter case currents were not measured.

15. Discharge currents ranging up to 3,700 amperes have been measured in the Wallenpaupack Thyrite lightning arresters. Prior to arrester installation, an average of one flashover per year occurred on each of the three $42^1/_2$-inch spillway gaps. None have occurred on arrester-equipped phases during their five years of use.

The Application of Class B Insulation to Auxiliary-Type D-C Motors in Severe Duty Service

F. A. COMPTON, JR.
ASSOCIATE AIEE

IN three papers[1,2,3] recently presented before the AIEE the life characteristics of class *A* insulation were discussed along with the rating, duty cycles, temperature measurements, and application of class *A* insulated induction motors. It is believed that a paper covering the application of class *B* insulation to electric motors would be in order. This paper is intended to show the advantages of class *B* insulation for certain applications, especially in d-c motors for severe duty service. The d-c motors covered by this paper are for:

1. Steel-mill auxiliary drives (totally enclosed and forced ventilated): screwdown, manipulators, side guards, table, shear, pinch roll, cranes, etc.
2. Electric shovel motors (both self-ventilated and forced ventilated): hoist, crowd, and swing
3. Other applications (enclosed, self-ventilated, and forced ventilated): dredges, hoists, cranes, and oil-well drilling rigs

In the d-c motors used in the several services outlined above it is of prime importance that the winding insulation be of such material and construction that long winding life and trouble-free service will be realized. This is especially true in some of the auxiliary steel-mill drives, as well as on electric shovels and gold dredges where a few hours delay as the result of insulation failure may cause a loss of an amount many times the price originally paid for the motor.

To put all motors on a standard, consistent, and reliable basis of rating, it is suggested in this paper that the resistance method of determining temperature rises on d-c severe-duty motors, based on higher temperatures fully to utilize the advantages of class *B* insulation as explained in this paper, be adopted as the preferred method, instead of the currently accepted thermometer method, as the basis for rating motors. The present thermometer method would, no doubt, be continued as an alternative method for a period of time because of the many motors now rated on that basis.

Once an accurate method of determining temperature rise has been standardized, it remains but to give the user operating recommendations relative to magnitude and time of overloads to the end that a motor may be properly applied and the user profit by obtaining the full economic life of the winding insulation.

The data presented in this paper are necessarily of a somewhat theoretical nature due to the lack of exact information in regard to the life of class *B* insulation at widely different temperatures.

For a proper understanding of the information given in this paper it must be remembered that this paper is written as applying particularly to auxiliary steel-mill motors, electric-shovel motors, and other applications as given in the first paragraph. The discussion that follows is not intended to apply to other classes of machines where the type of construction and nature of application differ.

Classes of Insulation

The two common types of insulation used in electric motors, and as described in the AIEE Standards, are:

1. *Class A*. Class *A* insulation consists of cotton, silk, paper, and similar organic materials when impregnated or immersed in oil; also enamel as applied to conductors.
2. *Class B*. Class *B* insulation consists of inorganic materials such as mica and asbestos in built-up form combined with binding substances. If class *A* material is used in small quantities in conjunction for structural purposes only, the combined material may be considered as class *B*, provided the electrical and mechanical properties of the insulated winding are not impaired by the application of the temperature permitted for class *B* material. (The word "impair" is here used in the sense of causing any change which could disqualify the insulating material for continuous service.)

Class A Insulation

Before attempting to point out the need for class *B* insulation on some applications of d-c motors it might be well to consider the merits of class *A* insulation.

The salient advantages distinguishing class *A* insulation from the class *B* type are:

1. Lower first cost. If two motors of similar construction and the same torque rating be compared, one of which is built with class *A* insulation to operate at allowable class *A* temperature rise, and the other built with class *B* insulation to operate at allowable class *B* temperature rise, it will be found that the class *A* insulated motor will be larger physically, but the difference in cost will not be proportional to the weight, because of the less expensive class *A* materials. In the case of small shunt motors, the cost of the somewhat larger class *A* insulated motor might even be the same or less.
2. Greater flexibility and tensile strength. Class *A* materials, such as cotton tape and varnished cloth, are quite flexible and may be wrapped tightly around corners without damage to the varnish film or cotton fibers.
3. Superior adaptability to the insulation of irregular shapes. By virtue of (2) above, class *A* material can be readily applied to irregular shapes such as channels for pole pieces and head insulation for armature

Discussion

For discussion, see page 1098.

back-end windings. Class *A* insulation in the form of phenolic resins with a cloth or rag base can be molded onto metal parts of very irregular shapes.

The greatest disadvantage of class *A* insulation is that by virtue of its chemical and physical properties, all of its apparent merits are nullified when the insulation is subjected to high temperatures for any appreciable length of time.

It has been pointed out elsewhere[1] that the life of class *A* insulation varies exponentially with the temperature to which it is subjected. A rough rule based on laboratory tests and extensive service experience is that the life of class *A* insulation is reduced to one half for each increase of 8 degrees centigrade in temperature, and that the total life at a continuously maintained temperature of 100 degrees centigrade is of the order of ten years. The 105-degree-centigrade hot-spot temperature allowed by the AIEE standards for class *A* insulation corresponds to an expected life of seven years. Thus, if class *A* insulation were subjected to a temperature of 150 degrees centigrade the life would be reduced to about $^1/_{64}$ of ten years (approximately two months) and under temperature conditions of 180 degrees centigrade the anticipated life would be but four days.

Class B Insulation

Class *B* insulation as applied to the d-c motors covered by this paper consists of either mica or felted-asbestos conductor insulation and mica ground insulation with an outside taping of asbestos. "Fiberglas" insulation is sometimes used in place of asbestos. The amount of class *A* structural material used in the class *B* insulation generally consists of thin sheets of paper or cloth to hold the mica splittings in place during the process of insulating and assembling the windings, along with the insulating varnish which fills the air spaces in the asbestos or Fiberglas taping. Field coils are generally impregnated with an asphalt-base compound.

The principal advantages of class *B* insulation over class *A* insulation are:

1. Ability to withstand high operating temperatures. The prime reason for using class *B* insulation is its ability to withstand high operating temperatures for long periods of time. Inherently, neither mica nor asbestos is affected by the high operating temperatures to which motor insulation is subjected. The class *A* structural material and the insulating varnishes used in class *B* insulations may be practically destroyed by excessive temperature over long periods of time but the remaining mica and asbestos will still give service if the insulation is held securely. Discussion in this paper is confined to class *B* insulation of the types used for d-c machines of normal voltage rating for steel-mill auxiliary drives and other applications previously outlined, where experience has shown that the mica insulation remains in place even after the destruction of the class *A* bonding material. The principles given may not be applicable to other classes of machines.

2. Greater mechanical strength of mica. Mica will withstand compressive stresses and abrasion better than any class *A* insulating material. All coils are subjected to concentrated pressures and abrasion during the following processes:

(*a*). Winding, insulating, handling, and assembling of coils in the motor
(*b*). Frequent starting of the motor
(*c*). Vibration during operation
(*d*). Expansion and contraction of windings from heating and cooling
(*e*). Rotation of armature resulting in centrifugal forces on the coils

Varnish film tends to distribute the normal pressure on coils and when this film is destroyed the insulation is subjected to concentrated pressures. The ability of mica to withstand high concentrated pressures without mechanical breakdown and subsequent dielectric failure makes it a valuable asset to coil insulation.

3. Moisture resistance. The moisture resistance of class *B* insulated coils with mica insulation is superior to class *A* coils. Class *A* coils depend entirely on the integrity of the varnish film to resist moisture absorption. Class *B* insulated coils depend primarily on the varnish film but not entirely. After the varnish film has dried out and cracked, due to service conditions, openings conducive to the entrance of moisture will be in evidence regardless of the type of insulation employed. The entrance of moisture to the conductors of class *B* insulated coils should be considerably less and at a slower rate than into the class *A* insulated coils because the individual mica splittings are impervious to moisture. The only way the moisture can penetrate the coil is by traveling the long creepage path between the laps of the mica tape.

All motors are subjected to moisture which is prevalent in the atmosphere to a greater or lesser degree. Since class *B* insulated motors normally operate at higher temperatures than class *A* insulated motors, there will be less tendency to moisture absorption by the class *B* insulation while the motors are at operating temperature. During idle periods moisture will be absorbed by either type of insulation. Upon the resumption of operations the moisture in class *B* insulation will be evaporated more readily because of the higher operating temperature under which the class *B* insulated equipment is operated.

Overload and Temperature Limitations

D-c motors for severe-duty service have relatively high torque capacity. It is possible for a d-c compound- or series-wound motor to develop more than ten times the normal torque obtained at the one-hour rating. Since it is possible to obtain such a high torque it is necessary to limit the torque to such values as will not cause damage to the motor. The generally accepted limiting torque values for 230-volt class *B* insulated motors for severe duty, expressed in terms of the one-hour enclosed rated torque (see appendix I) are:

Maximum starting torque:
500 per cent for series-wound motors
450 per cent for compound-wound motors
360 per cent for shunt-wound motors

Maximum running torque:
400 per cent for series-wound motors
350 per cent for compound-wound motors
300 per cent for shunt-wound motors

The maximum starting torque of the series-wound motor is limited by the mechanical construction of the motor, and principally by the shaft stresses and deflection, and bearing loads. The maximum running torque is limited by the commutating ability of the motor. The frequency with which the maximum torques are developed and the duration of time are both limited by the allowable hot-spot temperature in the motor.

Concomitant with the progress in the development of insulating materials to withstand higher temperature, and the wider knowledge of the service life of such materials, the natural trend in new designs would be to assign higher ratings based on the higher temperature and at the same time to provide the necessary mechanical strength and commutating capacity. This procedure would allow greater loads to be applied to a given size of motor so that the user could better realize the full economic life of the insulation.

There are some applications of auxiliary d-c motors in steel mills where the high ambient temperature makes it imperative to use class *B* insulation, for example, many roll drives, screwdowns, ladle cranes, and other drives. The high ambient temperature would leave little room for temperature rise in the motor windings if class *A* insulated motors were used and operated at the permissible hot-spot temperature of class *A* insulation. It is imperative that all of the above-mentioned motors be either totally enclosed or forced ventilated with clean dry air, because of the dirt, moisture, and fumes in the atmosphere. Quite often it is not feasible to force-ventilate these motors with clean air, and in view of this it is necessary for all of the heat produced by the motor losses to be dissipated from the external surface of the motor. If a class *A* insulated motor were used in place of a class *B* insulated motor the motor would have to be considerably larger to hold the temperature rise down to that permissible for class *A* insulation. The higher the ambient temperatures the greater is the ratio of the allowable temperature rise of class *B* insulation over that of class *A* insulation, maintaining their same respective allowable hot-spot temperatures.

The temperature rise of a d-c totally enclosed motor is assumed to be roughly proportional to the watts loss per square inch of surface. The allowable temperatures and rises as given in the AIEE standards are:

	Class A	Class B
Limiting hot-spot temperature (deg C)	105	125
Limiting observable temperature by resistance method (deg C)	95	115
Limiting observable temperature rises by resistance (deg C) (based on 40 deg C ambient)	55	75

With a 40-degree-centigrade ambient and a given duty cycle the class *A* insulated motor could have a rise by resistance of 55 degrees centigrade and the class *B* motor a rise by resistance of 75 degrees centigrade. From the ratio of 75/55 or 1.36 it is found that the class *B* insulated motor can dissipate 36 per cent more watts per square inch than the class *A* insulated motor. If a 60-degree-centigrade ambient be assumed the rise by resistance of the class *A* insulated motor becomes 35 degrees centigrade and that of the class *B* insulated motor 55 degrees centigrade, and the ratio of 55/35 or 1.57 indicates that the class *B* insulated motor can dissipate 57 per cent more watts per square inch than the class *A* insulated motor. As the difference in watts per square inch increases, so do the size and weight of the class *A* insulated motor increase over those of the class *B* insulated motor, although not in direct proportion. Quite often an increase in size and weight of a motor will make its application uneconomical.

In applications where starting and stopping constitute a major portion of the duty cycle, the rotor WR^2 must be considered in choosing the proper motor to perform the service required. When class *B* insulated motors are designed to operate at the allowable class *B* temperature rises a lower WR^2 is possible, as less active material is required than if the motor were designed to operate at allowable class *A* temperature rises. In applications requiring rapid acceleration and deceleration, the WR^2 of the motor often represents an appreciable portion of the total WR^2 involved. By reducing the motor WR^2, through the use of class *B* insulation, the whole drive can be accelerated and retarded in less time. Also, by reducing the total WR^2 of the drive, the actual root-mean-square load of the duty cycle is reduced. Thus class *B* insulation serves a twofold purpose—it reduces the motor heating and it enables the motor to withstand a higher temperature rise.

In service such as that encountered in steel mills and on electric shovels, overloads are applied to the motors with great frequency. Some of these overloads are part of the normal cycle of operation and some of them are accidental and unpredictable. An overload which would increase the temperature rise on a class *B* insulated motor to twice its allowable rise would do less damage to the class *B* insulation than the same per cent overload for the same length of time on a class *A* insulated motor would do to the class *A* insulation; that is, a 150-degree-centigrade rise (or 190-degree-centigrade temperature) will take less life out of class *B* insulation than a 110-degree-centigrade rise (or 150-degree-centigrade temperature) will take out of class *A* insulation.

Class *B* insulation also plays an important role in the rewinding of motors that were originally designed and applied with class *A* insulation, where it is desired to increase the duty cycle to such an extent that the class *A* insulation would have an uneconomical life.

From the foregoing advantages and uses it can be seen why class *B* insulation plays such an important part in helping to maintain continuity of service under operating conditions involving extreme dirt, moisture, vibration, high ambient, and overloads.

The expected life of class *A* insulation as previously mentioned, is approximately seven years at 105 degrees centigrade; that is, if class *A* insulation is steadily maintained at a temperature of 105 degrees centigrade, tests indicate that the insulation will reach the end of its useful life theoretically in seven years, or at the end of that period be subject to immediate failure under any mechanical or electrical shock. Such a life curve based on tests is not available for class *B* insulation. Although the AIEE standards allow the hot-spot temperature for class *B* insulation to be only 20 degrees centigrade greater than for class *A* insulation, actual service tests on some railway motors have shown the peak operating temperature to be from 180 to 200 degrees centigrade as measured by resistance. In one particular case some class *B* insulated machines were found operating in an 80-degree-centigrade ambient with a peak temperature of over 200 degrees centigrade and had been operating under these conditions for an appreciable length of time without insulation failure. It is not recommended that class *B* insulated motors operate at peak temperature of 200 degrees centigrade but it is known that there are many applications of class *B* insulated motors and generators where the peak temperature of the windings exceeds 200 degrees centigrade and the average operating temperature exceeds 150 degrees centigrade and the windings give long satisfactory service.

If, for some reason or other such as an emergency condition or through some fault, a class *B* insulated motor is called upon to operate at prolonged excessive overloads that result in abnormally high winding temperatures, the class *A* structural material will be destroyed, but the life of the remaining class *B* insulation can be greatly prolonged simply by dipping the armature or field coils in insulating varnish.

It would be a rather difficult problem to establish a life expectancy curve for class *B* insulation as has been done for class *A* insulation, because different amounts and kinds of class *A* structural materials are used by the various electric-motor manufacturers. There are many kinds of so-called class *B* insulations. In general, the class *B* insulation with the least amount of class *A* structural material should have a greater allowable hot-spot temperature for the same length of life. This applies to the d-c motors discussed in this paper and not to large high-voltage machines. The general tendency is toward the use of less class *A* material for structural purposes and better grades of insulating varnish which will maintain their desirable qualities at higher temperatures.

The 125-degree-centigrade hot-spot temperature, which is allowed for class *B* insulation according to the AIEE standards, therefore, seems too conservative for class *B* insulation as applied to d-c motors of normal voltage rating in severe duty service. That is, if such class *B* insulation be subjected continuously to a temperature of 125 degrees centigrade, a life expectancy far in excess of the seven-year life expected of class *A* insulation at 105 degrees centigrade would be in order.

In order to show the relation that exists between overloads and allowable temperature rise it is assumed that the life-expectancy curve for class *B* insulation varies exponentially with time in a manner similar to that of the curve for class *A* insulation. It is also assumed that this curve passes through the point of ten years at 125 degrees centigrade, and that the slope or exponent is such that the life of the class *B* insulation is reduced by 50 per cent with each 12-degree-centigrade increment of temperature. This assumed life curve is shown in figure 1, with the life curve for class *A* insulation. Available information on the expected life of class *B* insulation is rather meager, but from the few laboratory tests that have been made on samples of class *B* insulation as applied to d-c severe duty motors and the knowledge of operating temperatures on some applications of transportation motors, it is felt that the assumed life characteristic of class *B* insulation is very conservative. It must be remembered that this life curve (figure 1) for class *B* insulation is an assumed curve for purposes of discussion and to show the general relation existing between overloads and allowable temperature rise. The curves derived from the class *B* curve, figure 1, are not intended to show actual values that may be used in the application of any motor.

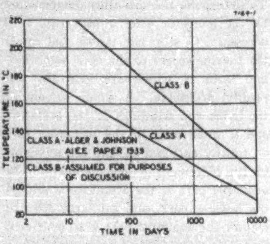

Figure 1. Life expectancy versus temperature for class A and class B insulating materials in continuous service

From the assumed life curve for class *B* insulation it can be seen that if a motor is operated continuously or 100 per cent of the time, the allowable hot-spot temperature rise for a 40-degree-centigrade ambient would be 85 degrees centigrade to give an expected life of ten years. The same motor operated only 50 per cent of the time, or on a long duty cycle of 50 per cent time on where the actual time of "power on" is three or four hours or more, may be operated in a 40-degree-centigrade ambient with a hot-spot temperature rise of 97 degrees centigrade and have an expected life of ten years. The additional 12 degree-centigrade hot-spot rise for one-half the time on would reduce the insulation life 50 per cent, but since the motor is operated for only one-half the time, the insulation would last ten years. This reasoning is based on instantaneous heating and cooling of the motor which, on account of the time lag of the temperature, is never realized, but is approached on long duty cycles.

The curves in figure 4* (see appendix II) indicate the advisability of using class *B* insulation in motors on applications resulting in a high ratio of peak temperature rise to average temperature rise, even though the average temperature rise does not exceed the maximum allowable rise for class *A* insulation, for example, if an application is assumed where the minimum permissible relative life of the motor insulation is 0.5 and the motor is operating with a ratio of average temperature to maximum allowable temperature of 0.8 (approximately 90 per cent of maximum continuous load), a change from class *A* insulation to class *B* insulation in the motor will permit the ratio of peak temperature to average temperature to be increased from 1.5 to 2.25 or 50 per cent. The corresponding increase in load will be about 25 per cent. The curves in figure 4 are based on a rectangular temperature cycle and instantaneous heating and cooling and are derived from the expected life curves for class *A* and class *B* insulation (assumed) in figure 1.

Since the aging effect on the insulation is less than assumed by instantaneous heating and cooling, greater loads may be applied for the same per cent "time on" to give the expected ten-year life. There are, however, two compensating errors both of which tend to offset the additional life due to temperature lag:

1. Increase of resistance with temperature causing greater watts loss for the same current load.
2. Starting current, which is generally greater than the running current during "power on", causes additional heating which has not been taken into account.

For cycles of short duration, for example, less than three or four hours, the effect of the temperature lagging behind the time becomes greater. This effect is shown graphically in figure 2 for a long and a short cycle. For relatively short cycles, each successive application of load to the motor raises the winding temperature less than the previous application. Each successive cooling period reduces the temperature more than the previous period. This process continues with each additional cycle until the temperature increase during "power on" equals the temperature decrease during "power off". For relatively long cycles, the temperature rise during "power on" approaches a constant value and the temperature lag has little or no effect on the motor heating. For long periods of "power on" and long cycles, the effect of temperature lag approaches that of instantaneous heating and cooling. Figure 3, curve 1, shows the permissible loading to give 90-degree-centigrade rise by resistance (peak rise) for a continuously repeated five minute duty cycle in which during the "power on" the starting amperes were equal to

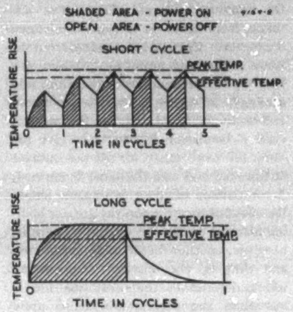

Figure 2. Effect of temperature lag on cyclic heating

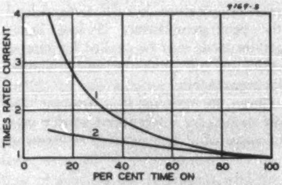

Figure 3. Permissible current loading of typical d-c totally enclosed motor in intermittent service for the same insulation life expectancy

Curve 1—For 90-degree-centigrade rise by resistance on a five-minute duty cycle. Based on tests with starting amperes equal to running amperes

Curve 2—For same insulation life expectancy as curve 1, but based on instantaneous heating and cooling, assumed life curve of class *B* insulation in figure 1, and ambient of 25 degrees centigrade the running amperes. This curve was taken from tests on a typical enclosed d-c motor. Curve 2 is estimated from the losses in the same motor but is based on a long cycle (instantaneous heating and cooling), 25-degree-centigrade ambient, and on the assumed expected life curve of class *B* insulation (figure 1) to give the same life expectancy for all percentages of time on, and also the same as curve 1. A comparison of these two curves shows the effect of time lag and the greater loading allowed on shorter cycles. There is, however, another factor to be considered and that is, the effective temperature which determines the insulation life is less than the peak temperature upon which curve 1 is based. The peak hot-spot temperature of curve 1 for a 25-degree-centigrade ambient would be 125 degrees centigrade (10 degrees centigrade allowed for hot-spot temperature above resistance temperature) which exists momentarily at the end of the "power on" part of the cycle. During the remaining part of the cycle the hot-spot temperature is less than 125 degrees centigrade. For 50 per cent time on (curve 1) the effective hot-spot temperature is approximately 120 degrees centigrade or 5 degrees less than the peak hot-spot temperature. This difference between the effective temperature and the peak temperature is so small for a five-minute cycle that it has been neglected in the comparison made on curves 1 and 2. For 100 per cent time on the difference between effective and peak temperature is zero and for 10 per cent time on it would be slightly greater than 5 degrees centigrade. As the time of the duty cycle is shortened, the effective temperature approaches the peak temperature, but for a given load the peak temperature is less, hence greater loads may be applied for shorter cycles and still obtain the same insulation life expectancy.

---

* Calculations for the curves of figure 4 as described in appendix II were made by T. C. Johnson, General Electric Company.

From the foregoing it is apparent that d-c motors for intermittent service may be operated at temperatures in excess of the allowable hot-spot rise and still have the same insulation life as though they were operated continuously at the allowable temperature. The amount of excess temperature rise depends on the following:

1. Ambient temperature—the lower the ambient temperature the higher the allowable rise
2. Per cent of "time on"—the lower the per cent of "time on" the higher the allowable rise
3. Heating time constant of motor—the greater the heating time constant the higher the allowable rise
4. Cooling time constant of motor—the less the cooling time constant, the higher the allowable rise

Figures 1, 3, and 4 are not intended to give actual values since they are based on an assumed expected life curve for class *B* insulation, which is felt to be conservative. These curves are intended to illustrate the general relations existing between the effects produced by the several variables that must be considered in applying a motor to a particular service.

Method of Temperature Measurement

The AIEE standards recognize three methods of temperature measurement in the rating of electrical machinery and apparatus.

1. Thermometer method—"This method consists in the determination of the temperature, by mercury or alcohol thermometers, by resistance thermometers, or by thermocouples, any of these instruments being applied to the hottest part of the machine accessible to mercury or alcohol thermometers."
2. Resistance method—"This method consists in the determination of temperature by comparison of the resistance of a winding at the temperature to be determined with the resistance at a known temperature."
3. Embedded-detector method—"This method consists in the determination of the temperature by thermocouples or resistance temperature detectors, built into the machine as specified in the section of the standards dealing with the specific kind of machine."

The basic standardized horsepower ratings of auxiliary-type d-c motors are limited to 75-degree-centigrade rise by thermometer.

This method of determining the temperature of d-c motors by thermometers does not give the most consistent results. The armature is generally the hottest, hence the limiting, part of the motor. To determine the armature temperature by thermometer after a heat run, it is necessary to stop the motor and apply the thermometers to the core and winding, both of which are generally not readily accessible. A small portion of the front end windings of the armature and a small area of the armature core on totally enclosed motors are available for the placement of thermometers. The available part of the armature is seldom the hottest part, and on some sizes of motors the available part is so restricted that it is quite difficult properly to place and to protect the thermometer bulb so that it gives a true indication of the actual temperature at that point. Even if the thermometer could be placed on the hottest spot, an intimate contact with the insulation made, and the thermometer bulb properly protected from the surrounding air, a certain time would be required for the thermometer to register the temperature of the spot on which it is placed. While the thermometer is coming up to temperature, the temperature of the spot being measured may in some cases be falling. Hence the maximum temperature indicated by the thermometer may not always be the temperature at the end of the heat run. This time lag of thermometers can be reduced by preheating the thermometer to about 10 or 20 degrees centigrade less than the anticipated thermometer temperature.

Temperature measurements by the resistance method can be conveniently and accurately made, and, when properly made, give very consistent results. There are certain precautions that must be observed in measuring the winding resistances, such as using the proper type of bridge; separate voltage and current leads, and making sure that all connections are clean and tightly made. In addition, when determining the cold resistance or resistance at a known temperature good practice dictates the placement of thermometers on all windings to be measured and the taking of resistance measurements only when the thermome-

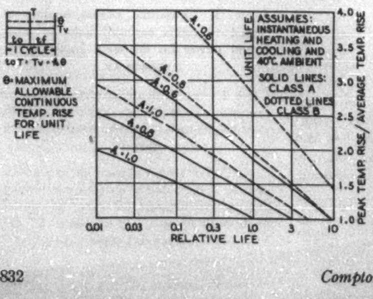

Figure 4. Comparison of relative life of class A and class B insulation for rectangular temperature cycles having same average temperature for different percentages of the maximum continuous temperature based on life expectancy curves figure 1

ters on the windings are within three degrees centigrade of the ambient temperature. If the difference between the winding temperature and ambient temperature is much greater than three degrees, the winding resistance is changing and an error in cold resistance is likely to be introduced.

At the end of a heat run the stopping of the motor and the measurement of the resistance of all windings can be accomplished in one to two minutes time. Thus determination of the temperature of an armature winding by the resistance method in much less time after shutdown is possible than by the thermometer method (thermocouple excepted). From resistance readings taken at various intervals after shutdown a cooling curve of temperature versus time can be plotted. By extrapolation of this curve back to zero time, actual winding temperature at the time the power was cut off can be determined.

In a previous paper[3] a very complete discussion is given on the advantages of the resistance method over the thermometer method of determining temperatures, with supporting evidence taken from tests on various induction motors, which show the possible inaccuracy of the thermometer method and the accuracy and consistency of the resistance method.

The AIEE standards are based on a certain allowable hot-spot temperature, which for class *B* insulation is 125 degrees centigrade. This hot-spot temperature determines the life of the winding insulation. Since it is not convenient or practical to measure the hottest spot in a winding, the AIEE standards specify a "conventional allowance" by which the observable temperatures are assumed to be lower than the "hottest spot" temperatures. The conventional allowances in degrees centigrade are:

Thermometer method	15
Resistance method	10
Embedded-detector method	5

Since it is recognized that there is less difference between the hottest spot and the resistance temperature than between the hottest spot and the thermometer temperature, it follows that the resistance temperature would give a truer indication of the insulation life than the thermometer temperature.

A study was made of the difference between thermometer and resistance temperature rises from 91 different heat runs made on ten different frame sizes of d-c class *B* insulated totally enclosed auxiliary-type steel-mill motors. Each heat run was made for a definite length of time starting cold with the motors loaded to give approximately 75-degree-centigrade rise by thermometer on the hottest winding, which in all cases, was the armature. The per cent difference between the rise by resistance and the rise by thermometer plotted against length of time of heat run is shown for one size of motor in figure 5.

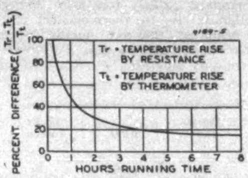

Figure 5. Relation of per cent difference of resistance rise over thermometer rise for various lengths of heat runs

In all cases the rise by resistance is greater than that by thermometer. The general shape of this curve is characteristic of the curves obtained on all sizes of motors tested. However, the smaller motors show flatter curves, and the larger motors show slightly steeper curves. The general range of resistance rise minus thermometer rise for one-hour heat runs was 10 to 35 degrees centigrade for the various frame sizes, while for eight-hour heat runs the range was from 5 to 15 degrees centigrade.

With the present practice of rating d-c motors on a 75-degree-centigrade-rise-by-thermometer basis, a greater rise by resistance is obtained on the short-time 15-minute or 30-minute ratings than is obtained on the one-hour or five-hour ratings. This is not quite so inconsistent as it may appear because the short-time-rated motors are applied on duty cycles with less per cent "time on" than are the longer-time-rated motors. In the foregoing discussion on overload and temperature limitations it was pointed out that with less per cent "time on" for a given duty cycle the allowable temperature rise is greater for the same expected insulation life.

Continuous heat runs on ventilated motors in contrast to totally enclosed motors, show resistance rises exceeding thermometer rises over a range of from 20 to 50 degrees centigrade depending on the size of motor and type and amount of ventilation. The ratio of the rise by resistance over the rise by thermometer will increase as the amount of ventilation is increased.

Figure 6 shows graphically the general relation of the input watts to the watts dissipated. The area under the input curve represents the energy input in losses while the area under the dissipated curve represents the energy dissipated. The difference between these two areas represents the energy absorbed which raises the temperature of the winding and is an indication of the winding temperature as measured by resistance. The amount of watts being dissipated at the end of the heat run is an indication of the surface temperature of the insulation as measured by thermometer. Approximate relations of watts loss to copper and insulation temperature rises are given in appendix III.

Although all frame sizes of motors are rated on the same basis, that is, 75-degree-centigrade rise by thermometer, the actual rise by resistance is greater than 75, and the amount the resistance rise exceeds the thermometer rise varies for different frame sizes. The larger motors, in general, have a greater rise by resistance than the smaller motors for the same rise by thermometer.

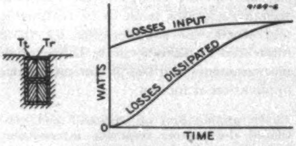

Figure 6. Relation of losses input and dissipated to time

See appendix III

The International Electrotechnical Commission has recently adopted the resistance method as standard for electric traction motors. The following method of determining the motor temperatures at time of shutdown was agreed upon according to the minutes of the meeting held in Torquay on June 22, 23, and 25, 1938. The measurement of resistance of the armature shall be made in a time less than, or equal to, $1^1/_2$ minutes from the time of shutting off the current, and the other resistance measurements on fixed windings shall be made within a maximum time limit of 2 minutes. The temperature rise at the moment of cutting off the load to be determined by linear rectification of the first part of the cooling curve (first 5 minutes) plotted by using a logarithmic scale for the temperature rises and a linear scale for the time.

The resistance method of temperature determination for railway motors has been adopted by the AIEE and it seems reasonable that the same method should be adopted for the d-c motors covered by this paper.

In order that

1. The temperature rating of d-c motors for severe duty service gives a more accurate indication of the actual temperature within the winding at the time of shutdown.

2. The temperatures of the windings may be more accurately and conveniently measured, whether on the test stand or in service.

3. The user may be assured that nameplate temperature rises are measured on a more consistent and comparable basis.

4. Any controversy over how, when, and where to place thermometers to determine winding temperatures may be eliminated.

It is recommended that the resistance method of determining temperature rise be adopted as the preferred standard for both totally enclosed and ventilated d-c motors for severe duty service.

Conclusions

In view of the arguments and exhibits set forth in the foregoing, the following recommendations seem to be reasonable and worthy of consideration by those interested in more accurate temperature measurements and the proper rating and application of motors.

1. In applications on enclosed and ventilated d-c motors requiring intermittent high torque (high ratio of peak torque to rms torque) or severe duty of any kind, full use of the torque capacity, operation in extremely high ambients, or in damp atmosphere or locations, the use of class *B* insulation seems advisable.

2. For future standards adopt resistance method of determining winding temperatures as adopted for railway motors.

3. If resistance method is used, substitute some higher value than the present AIEE 75-degree-centigrade rise, such as 105 to 120 degrees centigrade by resistance, as the basis for establishing the basic ratings.

4. A possible method of rating would be to adopt the one-hour rating based on the rise by resistance, and have operating recommendations, giving curves of permissible overloads for different percentages of "time on" with same years of life and various lengths of duty cycles.

Appendix I

Standard ratings (one-hour 75-degree-centigrade rise by thermometer) of class *B* insulated 230-volt totally enclosed series-wound auxiliary-type d-c motors for severe-duty service:

Horse-power	RPM	Lb-Ft Torque
5	900	29
7 1/2	800	49
10	725	72
15	650	121
25	575	228
35	525	350
50	500	525
75	475	830
100	460	1,140
150	450	1,750

Appendix II

In order to show the effects of increasing peak temperatures in duty cycles where the rms load is held constant let it be assumed that temperature rise is proportional to the square of the load; this means a comparison of temperature cycles with the same average temperature. Figure 4 shows the relative life of class *A* and class *B* insulation as a function of the ratio of peak temperature rise to average temperature rise for the same average temperature for various values of k, which is the ratio of average temperature rise to the maximum allowable rise for unit life on class *A* insulation. These curves are based on the life-expectancy curves of figure 1, instantaneous heating and cooling, rectangular load cycle at 40-degree-centigrade ambient, and a unit life of 9.2 years at 102 degrees centigrade for class *A* insulation. The curves show the permissible increase in ratio of peak to average temperature when the insulation in a motor is changed from class *A* to class *B* with no other changes. The solid lines are for class *A* insulation and the dotted lines for class *B* insulation and based on the assumed life curve of class *B* insulation figure 1.

Appendix III

Figure 6 shows the relation of the input losses and dissipated losses as a function of time. The difference in watts between these two curves represents the watts absorbed and the area between the two curves represents the watt-hours of energy absorbed by the winding which raises the copper temperature. For any length of heat run, if the rise by resistance is known the difference between the rise by resistance and rise by thermometer (on surface of insulation) can be approximated from the following relations:

T_r = temperature rise of copper—as measured by resistance

T_t = temperature rise on surface of insulation—as measured by thermometer

Watts input = watts absorbed + watts dissipated

$$T_r = \frac{\text{watt-hours absorbed}}{0.0495 \times \text{pounds copper}} \text{ in degrees centigrade}$$

$$(T_r - T_t) = \frac{\text{watts dissipated} \times L}{0.528 \times k \times A} \text{ in degrees centigrade}$$

A = area in square feet of dissipating surface

L = length of path in inches

k = thermal conductivity in Btu per hour per square foot per degree Fahrenheit per inch

New Developments in Current-Transformer Design

G. CAMILLI
MEMBER AIEE

Synopsis: In the past, instrument transformers, with few exceptions, have been designed along the lines of small power transformers and have frequently been unnecessarily bulky with other disadvantages which necessarily attend bulk. This paper describes a new line of high-voltage current transformers with relatively novel principles of construction by means of which volume and weights have been cut down by about a half and factor of safety increased, while more than meeting the NEMA standards of accuracy.

This accounts for the appearance of these transformers as mostly bushings. The most striking novel feature of construction of these transformers is the adoption of the highly efficient method of cable insulation to them by so arranging and shaping the design that the major insulation between the two windings is a closed torus with no ends and hence free from creepage problems. The execution of this ideal is made possible by designing the bushing as a truly integral and inseparable part of the transformer. Other features of these transformers include Spirakore magnetic circuits of exceptionally high magnetic performance, and adaption of the new method of insulation to "cascade" designs.

VERY noteworthy progress has been made in recent years in the design of current transformers for medium and high voltages. Previously most current transformers were designed and built according to the same general practices as a small power transformer, and its size, weight, and general appearance was that of a conventional transformer. The latest current transformers, described below, scarcely resemble their predecessors—their weight, size, etc., are but a small fraction of the older designs. A comparison of the principal data of two current transformers—one designed in 1929 and the other of recent development—may be of interest (table I).

For comparative outlines of the two transformers see figure 1.

The transformers compared in table I are of "single-stage" type, that is, they consist of a primary (high-voltage) winding and a secondary (low-voltage) winding fully insulated from each other. Progress has also been made in the design of those transformers in which the major insulation is subdivided into stages (cascade type).

Table II gives the comparison between the conventional transformers and two transformers of the cascade type, one designed in 1935 and the other of recent design.

The progress made in the design of current transformers for medium and high voltages can be best explained in the light of the progress made in the method of insulation; and the very new developments made in the manufacture of a wound core transformer under the trade name of "Spirakore".

Insulation

The high-voltage winding of a current transformer consists of a coil (having one or more turns), fully insulated from the low-voltage winding at ground potential.

In the high-voltage coil the insulation between turns is easily provided for. Consequently the coil may be considered as a single conductor which is insulated from ground. The analogy between this problem and that occurring in the design and manufacture of cables for medium and high voltages is apparent.

In the development of the new type of insulation advantage has been taken of the refined technique of the high-voltage cable design.

Referring to figures 2, 3*a*, and 3*b*, the high-voltage coil is enclosed in a split hollow metal ring which leads to a pipe which encloses the terminals of the coil. The coil, the enclosing ring, and the pipe are electrically connected together and therefore are at the same potential.

The writer gratefully acknowledges his profound indebtedness to many of his associates (too numerous to list here) both in the engineering department and the insulation research laboratories of his company.

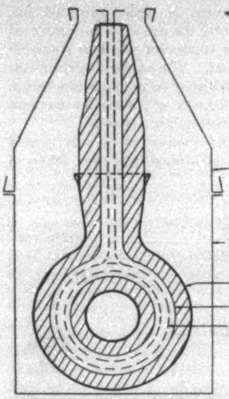

Figure 2. Schematic drawing showing assembly and high-voltage insulation of a new type current transformer described in the text

The problem of insulating the ring and the pipe is similar to that of insulating a high-voltage oil-filled cable, in that the insulation consists of crepe paper impregnated with mineral oil. This paper is lapped helically on the high-voltage sheath (ring and pipe) in the form of strips. After the required thickness of paper has been applied, the portion containing the high-voltage coil (figure 2) is covered with a metallic screen or shield which is connected to ground. This screen is equivalent to the lead sheath of the ordinary cable. The similarity between this type of construction and the well-known oil-filled cable is evident.

Figure 3a. View of high-voltage shield which enclosed high-voltage winding

Figure 3b. View of the high-voltage coil and casting

The grounded coil is ordinarily placed inside a small steel tank (figure 2), while the lead-in is placed inside a porcelain shell (bushing)—the performance of the latter being similar to the pressure reservoirs of the oil-filled cable. The hollow pipe allows the oil to flow out into the bushing when the load increases and to flow back when it decreases. Void formations in the insulation are entirely suppressed under working conditions. Needless to say, the transformer is hermetically sealed.

By proper choice of paper and a very careful heat vacuum treatment, a very flat power factor/temperature curve is obtained, and the danger of thermal instability is eliminated. However, manufacturing procedure dictates that the maximum dielectric gradients used in the design of current-transformer insulation of this type be of somewhat lower values than those used in cable design.

The "Spirakore" as Applied to Current Transformers

While the accuracy of a potential transformer is primarily a function of its impedance characteristics, the exciting current is the primary cause of current transformer errors. Any reduction in the exciting current will improve the accuracy of current transformers.

The magnetic properties of the Spirakore[3] when used in conjunction with the type of high-voltage construction just described, seem ideal for current-transformer applications. In this type of core, with the grains rolled in the same direction as the working flux, the hysteresis loss has been reduced to the very minimum, commensurable with the type of core material used. The elimination of the joints (which are present in the conventional core), has increased its accuracy up to the overload working range of the current transformers.

Referring to figure 4*a*, the annealed core is rewound over the ground shield to link the high-voltage coil, and then the turns of the low-voltage coil of the current transformer are evenly distributed over the circumference of the core. The latter feature is typical of the construction used in the manufacture of bushing current transformers.

It is recognized that the bushing-type current transformer has ideal characteristics, with the exception of the accuracy. With this new design the number of primary ampere-turns has not been limited to one, as in the usual bushing current transformer, and hence very high accuracy can be easily obtained. A method of compensation to increase the accuracy of the new transformers is discussed under the title of "Method of Compensation".

Current transformers for the highest voltages have now been designed, with the ideal characteristics of the bushing current transformer, using the insulation and construction previously described. Among the advantages of this combination it suffices to say that the secondary reactance of the current transformer is negligible, and as a result, the size and weight of the core are reduced to a minimum for a specified overload accuracy (see table I). Figure 4*b* shows a 230-kv current transformer built in accordance with the above principles of construction.

A slightly different form of construction is shown in figures 5*a* and 5*b*. The high-voltage winding in each case is wound directly over the core (which may have a cruciform cross section). In figure 5*a*

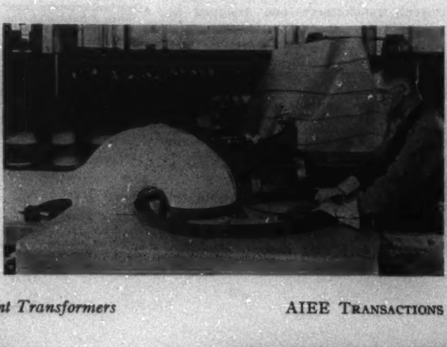

Figure 4a. Winding of the core over the insulated high-voltage coil

---

[3] For all numbered references, see list at end of paper.

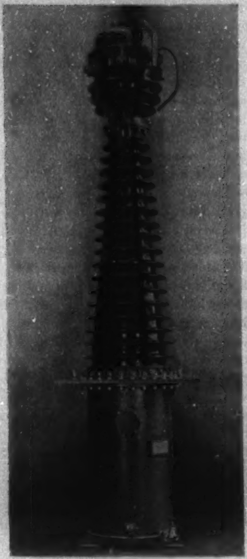

Figure 4b. View of a 230-kv current transformer using cable-type insulation and Spirakore wound over the ground shield of the high-voltage winding

suitable for low primary currents, the high-voltage winding is distributed directly over the core. In figure 5*b* suitable for very high current, the primary current is first stepped down by means of a small auxiliary current transformer which is maintained at high potential and therefore is placed on top of the current transformer. The low-voltage winding is distributed over the ground shield of the transformer. In this type of construction there is an internal secondary reactance which is in series with the burden and therefore, in order to obtain the same degree of accuracy as the scheme shown in figure 2, larger cores are necessary.

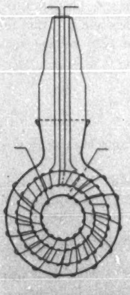

Figure 5a (left). Schematic diagram of a new design current transformer for low primary currents

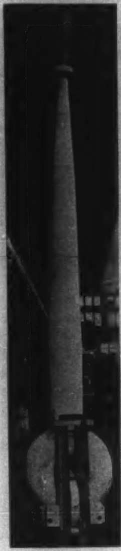

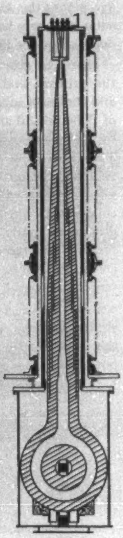

Figure 6 (left). View of the 287-kv current transformer proposed for the Boulder Dam line

Figure 7a (right). Cross section of a new-design current transformer proposed for the 287-kv Boulder Dam installation

This construction, although not as convenient as that of figure 2, will result in a small and compact transformer. A transformer proposed for the 287-kv Boulder Dam-Los Angeles transmission line,* is shown in figure 6 and in diagram figure 7*a*. Incorporated in the design are the same general principles of the new type insulation and Spirakore construction previously described. In addition, electrostatic shields have been applied to control the radial and longitudinal stresses in the lead, and tests have shown them to be very effective for both normal-frequency and impulse voltages. These shields are similar in principle to the shields of a capacitance bushing. The voltage distribution along the shields is shown in figure 7*b*. A sample of these transformers has been designed and tested to the following specifications:

One minute test....................650 kv
Dry flashover.......Not less than 780 kv
Impulse tests—Applications of two chopped waves, followed by one application of a full wave. Chopped wave should have a crest voltage of 1,595 kv and a maximum time to flashover of three microseconds. Full wave should have a crest voltage of 1,380 kv and no flashover of the transformer or gap should occur.

The transformers just described provide a satisfactory solution to the problem of high-voltage current-transformer design by putting the entire insulation which separates the high-voltage side from the grounded core, upon the primary winding. In a very high-voltage transformer the effective iron and copper are only a fraction of the total bulk of the materials incorporated in such designs. Any change in the construction which results in a substantial reduction in the amount of insulation required, will result in a correspondingly large reduction in the volume and weight of the transformer. For the very highest voltages some saving in the insulation may be obtained by us-

* The transformers which are used in the impulse breakers for the 287-kv Boulder Dam line are of the cascade type and are shown in figures 11 and 14.

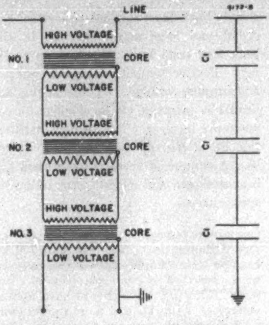

Figure 8. Elementary diagram of a three-voltage-step cascade current transformer

ing the "cascade principle".[4] The cable type of insulation has been extended to this type of transformer with good results, especially in reducing the size and increasing the accuracy of the apparatus. The principle of cascade-connected current transformers is similar to that employed in the so-called "chain connected" potential transformers.[5]

Figure 8*a* illustrates an elementary scheme comprising three subunits connected in cascade. The line-to-ground potential is divided among the three subunits in accordance with their series capacitances (figure 8*b*). If the three capacitances are alike, the major insulation of each subunit needs to be designed for only one-third of the line to ground potential, and each subunit may, therefore, be made correspondingly smaller than a conventional single-unit design.

A much more compact design than the foregoing can be obtained by the construction shown in figure 9*a*. Here also there are three subunits in cascade, but with this important difference—that the voltage across the major insulation of each subunit is only half of that of figure 8, or one-sixth of the line-to-ground potential.

It will be observed that in this design the primary and secondary windings *A* and *B* of each subunit are on opposite legs of the core and are coupled to each other by means of auxiliary windings *C* and *C*. The *A* winding of the top unit is connected to the line and is at line potential—whereas the *B* winding of the bottom unit connects to the burden with one side grounded, and is therefore at ground potential. The remaining windings and the cores are floating, and thus acquire potentials between line potential and ground.

From the practical standpoint, it is desirable that the subunits be designed for the same fraction of the line-to-ground potential. The voltage distribution among the subunits evidently depends upon the capacitance relationships. The capacitance circuit is shown in figure 9*b* and it is obvious that to enforce a linear distribution the capacitance *C* between each main winding and the core should be large compared to core-to-core, core-to-line, core-to-ground capacitances *K*, *C''* and *C'* respectively, so that *C* can dominate the distribution.

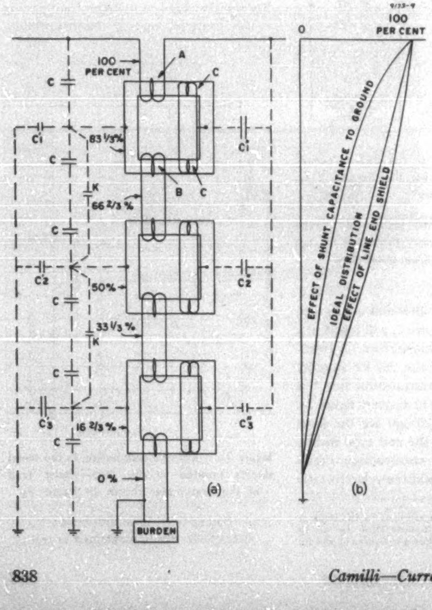

Figure 9. Schematic diagram of a cascade current transformer having six voltage-steps as shown in figure 11

The effect of shunt capacitances to ground is to cause a drooping distribution, just as on a suspension insulator string—while the effect of the capacitance to the line is to pull the distribution up (see figure 9*b*). It is theoretically possible to design a shield so that the line capacitance just neutralizes the shunt ground capacitance—thus allowing the series capacitance to determine the distribution, and indeed this is the principle used in the nonresonating transformer. But in the present application it is more feasible to obtain the desired linear distribution by making the coil-to-core capacitance very large compared with the other capacitances present. In some designs this end is secured by insulating the main windings from the cores with porcelain spools, "schooped" (sprayed with metal) on both sides so as to provide a large-surface high-permittivity capacitor. Consequently the distribution is substantially uniform and of course the distribution remains so under surge conditions.

The question naturally arises—in what way does such a construction result in a saving of insulation—and what is the criterion for the number of units? The strength of insulation is not a linear function of its thickness, but increases at a slower rate as thickness is increased. Thus, for oil the thickness of insulation varies as the 1.6 power of the test voltage. If therefore, the insulation required for a test voltage is $KE^{1.6}$, that required for the same test voltage subdivided into n steps, is

$$Kn\left(\frac{E}{n}\right)^{1.6}=\frac{1}{n^{0.6}}KE^{1.6}$$

and the ratio of the insulation thickness is $1/n^{0.6}$.

This ratio is plotted in figure 10. It is clear that a substantial reduction in total insulation thickness results from subdivision, but the curve is one of diminishing return and there appears to be little excuse for carrying subdivision any further than six steps, unless for other reasons—such as keeping the size of the units small enough to fit inside porcelain shells of given dimensions. Additional reasons for keeping the number of units to a minimum are that the accuracy may be

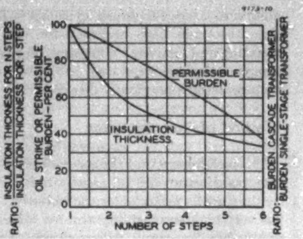

Figure 10. Ratio of insulation thickness and ratio of permissible burdens (to obtain a given accuracy) of a cascade current transformer and a conventional transformer for different numbers of voltage steps

seriously impaired by too many units (see figure 10) and that manufacturing objections increase.

Figure 11 shows an inside view of one of the current transformers which are integral parts of the Boulder Dam 287-kv impulse circuit breaker[6] shown in figure 12. These current transformers were built to withstand 650-kv 60-cycle test. The current transformers are in the outside supporting columns of the circuit breaker—two current transformers per phase being required. Each transformer has three units. Each unit has a core, two main windings, two coupling windings, and a number of compensating windings. The whole structure is supported and clamped by four Herkolite columns with angle-iron braces at the top and bottom. In this case the transformer is contained in an oil-tight Herkolite cylinder which also supports the weight of the circuit breaker.

The outside porcelain shell supports no weight and is equipped with a flexible bellows connection at the top to allow for expansion and contraction and mechanical adjustments in assembly. There is a Thyrite by-pass at the line terminals for surge protection.[7]

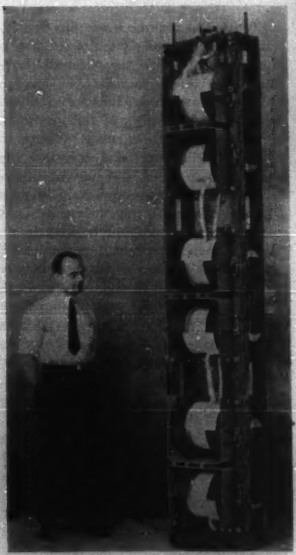

Figure 11. Cascade current transformer, 287-kv, installed in the impulse circuit breaker shown in figure 12

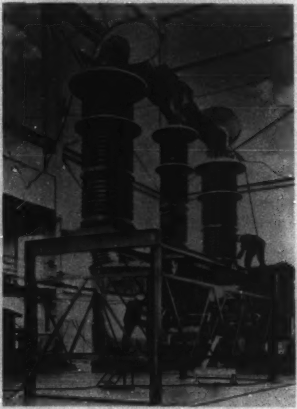

Figure 12. View of the 287-kv impulse circuit breaker

The two outside porcelains enclose cascade current transformers shown in figure 11

Figure 13 gives a comparative outline of the above current transformers with those of a conventional design and for the same voltage and rating; calling the conventional design 100 per cent, there is for the cascade type:

Height—40 per cent
Weight—18 per cent
Floor space—45 per cent
Oil—7 per cent

As mentioned previously the cable type of insulation has been applied to the cascade design also. The porcelain of the previous design has been replaced by oil-impregnated paper, and uniform large capacitances between stages have been obtained by enclosing the windings in metal shells. Uniform capacitance has thus been obtained regardless of dimensions of the windings.

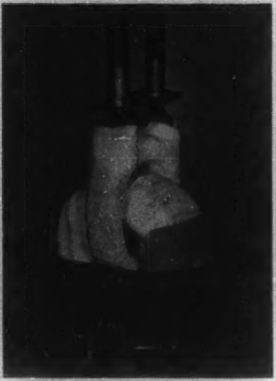

Figure 16. Shows core and coils, 15-kv current transformer assembled in the tank

vious porcelain design) to four. Likewise the size of the transformer has been reduced. Thus, while the preceding porcelain spool design was contained in a 24-inch-diameter Herkolite cylinder, the new transformers are enclosed in an 18-inch-diameter cylinder. No reduction is possible in the height of the transformers since the height is determined by the creepage and the flashover characteristics of the external porcelain shell (bushing).

Progress in Low-Voltage Current-Transformer Design

The new type of insulation also finds application in the lower-voltage classes. Figure 15 shows the comparison between the old- and the new-design current transformer for 69-kv circuit.

Figure 16 shows the core and coils of a new 15-kv current transformer, while figure 17 shows its external view. The porcelain shell has the shape of an inverted pot with two holes, through which are inserted the terminals of the high-voltage winding. Internally the high-voltage coil is insulated by crepe paper from the low voltage, evenly distributed on the Spirakore. The complete assembly is filled with a mixture of Pyranol and inorganic material through the hollow terminals of the high-voltage winding. The design of the 15-kv current transformer contains several features of special note. One of these is found in the construction of the core and coils as indicated in figure 15. In one method of construction the low-voltage winding is evenly distributed over the core and is partially insulated with crepe paper by a special winding machine. The high-voltage winding is pulled into a helix and screwed into a loop with the low-voltage winding. The turns making up the high-voltage winding are then closed together, and after connecting the terminals the coil is insulated with several layers of crepe paper.

In another method of construction the high-voltage winding is first insulated and the Spirakore is wound over it. The turns of the low-voltage winding are then uniformly distributed over the Spirakore. The well-recognized superiority of a circular coil for the high-voltage winding, to better withstand mechanical forces, has been maintained. The circular high-voltage coil passing through the center of the circular Spirakore with its distributed secondary winding, gives a transformer which approaches the ideal mechanical characteristics of the bushing-type current transformer. After being filled, these transformers are hermetically sealed, similar to the higher-voltage units. An adequate amount of free space is provided in the shell to accommodate the expansion of the liquid filler.

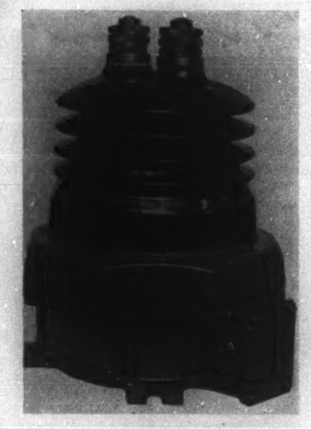

Figure 17. New design 15-kv current transformer

The low-voltage bushings of these new transformers shown in figure 18, should be mentioned. These are made of special glass which is fused in a metal shell which has exactly the same coefficient of thermal expansion as that of the glass under a very wide range of temperatures.

Another distinct advantage of the Spirakore construction is its unique adaptability to a special means of compensation to obtain high accuracy for both metering and relaying. The same type of compensation has been used in the high-voltage designs previously described.

Method of Compensation

It is well known that the errors of a current transformer can be greatly reduced by the use of a material for the core which has very high permeability and low losses at low flux densities.[8] Alloys of iron and nickel, especially those generally known under the name of "Permalloys" would be very desirable in the manufacture of current transformers if it were not for some disadvantages which will prevent their general use. Among these disadvantages, as compared with those of ordinary silicon steel, we may mention their high cost, their susceptibility to mechanical shocks, and the low saturation value.

Without resorting to special alloys other methods are available for the reduction of the exciting current and consequently of the errors of current transformers. Limiting our discussion to current transformers using cores made of silicon steel, it is well known that this material reaches the maximum permeability for values of flux density around 5,000 lines per square centimeter. Current transformers are normally used at a much lower flux density and consequently at a point of the saturation curve at which the permeability is much lower than maximum.

If the cross section of the core is reduced so as to reach at full load the maximum permeability, even for small variation in load, the reluctance, and therefore the exciting current of the current transformers, will increase very rapidly with the inevitable result that the errors of our current transformers will be very large. The ideal performance will be obtained if the permeability remains approximately at maximum value throughout the working range of the load current (normally from 10 per cent to 100 per cent). This can be obtained by adopting large cross sections for the core and "premagnetizing" it by some other current of the same frequency in such a manner that it has no influence on the current to be measured.

This auxiliary current must be such as to bring the magnetization of the core up

Figure 18. Bushing for secondary terminals of current transformers

to the region of maximum permeability. If the cross section of the core is relatively large, the magnetization of the iron due to the working flux is relatively small, and the variation of the flux density with variable load does not deviate too much from the value of maximum permeability.

To premagnetize the core it is possible to use[9] an auxiliary current furnished by an external source of the same frequency. To avoid the mutual effect of the two currents, the current of premagnetization and the current to be measured, the core is divided into two equal parts, which are magnetized by the auxiliary current in opposite direction.

Without going to a separate source for the auxiliary current, auxiliary magnetization may be furnished from a separate core (see figure 19), excited from the same current that is to be measured.[10] The number of auxiliary turns and the cross section of this auxiliary core are selected in such a manner that under average normal load conditions it is almost saturated, and therefore the auxiliary current which it furnishes to the main core of the current transformer changes very little during the working range of the current transformer.

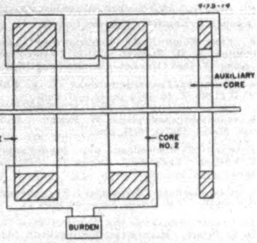

Figure 19. Schematic diagram of a current transformer separately excited by an auxiliary core

The above scheme represents a marked improvement in the normal (10 per cent to 100 per cent) working range of the current transformers. Under overload condition, however, the induction of the core reaches the point of saturation too soon and the errors of the current transformer increase too rapidly.

Instead of using an auxiliary core to furnish a current for the premagnetization of the working core of the current transformer, the auxiliary magnetizing current can be derived directly from the secondary current of the current transformer.[11] (See figure 20a).

The flux in each core is due to the result of the primary and secondary ampere turns. By the proper selection of the direction of winding and of the number of turns of the auxiliary windings in core 1, the ampere turns of the primary can be made to exceed those of the secondary, while in core 2 the secondary ampere turns can be made to exceed those of the primary. In other words, for core 1:

$$NI_1 = (N_s - n_2)I_2$$

and for core 2:

$$NI_1 = (N_s + n_3)I_2$$

The connections shown in figure 20*b* are equivalent to those of figure 20*a*, in which

$$N_s - n_2 = N_1$$

$$N_s + n_3 = N_2$$

Figure 21*a* shows the diagram of the ampere turns of a normal current transformer. Figure 21*b* shows the diagram of the ampere turns of core 1 of our premagnetized current transformer. In this core the primary ampere turns exceed those of the secondary, and the resultant ampere turns are:

$$I_1N + I_2N_1 = I_1W_1 \tag{1}$$

It should be noted that the resultant ampere turns in this core are approximately in phase with the primary ampere turns. Likewise figure 21*c* represents the diagram of the ampere turns of core 2. In this core the secondary ampere turns exceed those of the primary, and the resultant ampere turns I_2W_2 are approximately in phase with the secondary ampere turns according to the equation:

$$I_1N + I_2N_2 = I_2W_2 \tag{2}$$

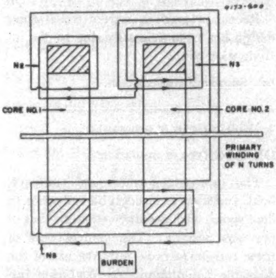

Figure 20a. Schematic diagram of a current transformer with auxiliary excitation derived from the secondary side of the current transformer

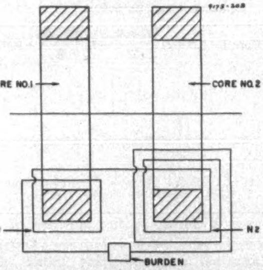

Figure 20b. Simplified diagram of the connections of the current transformer shown in figure 20a

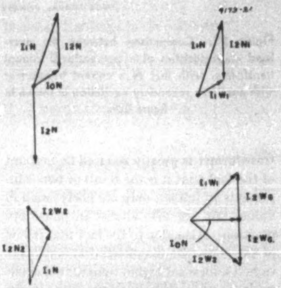

Figure 21. Diagram of the ampere turns of a current transformer with auxiliary excitation from the secondary current as shown in figure 20b

(*a*)—Vector diagram of the ampere turns in a normal current transformer

(*b*)—Vector diagram of the ampere turns in core number 1 of the transformer shown in figure 20*b*

(*c*)—Vector diagram of the ampere turns in core number 2 of the transformer shown in figure 20*b*

(*d*)—Resultant vector diagram of the transformer shown in figure 20*b*

For a given burden the induced voltage E_2 determines the value of the common flux ϕ in the two cores, and the no-load ampere turns of the current transformer.

The above no-load ampere turns are the result of the two ampere turns I_1W_1 and I_2W_2. Due to the fact that the two ampere turns I_1W_1 and I_2W_2 are almost in phase opposition, each one must be much larger than the no-load ampere turns of the current transformer. Their value is such that the flux density in the two cores in the region of maximum permeability is increased. (See appendix I.) It follows that the exciting current of the current

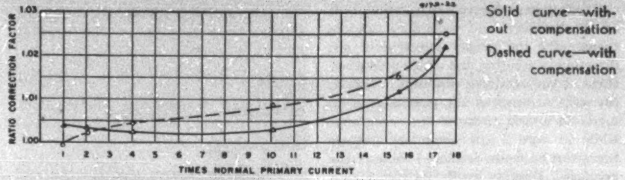

Figure 22. Comparison between the overload characteristics of a conventional current transformer with that of a current transformer with auxiliary secondary excitation as shown in figure 20b

transformer is greatly reduced on account of the fact that it is the result of two components which not only are fairly small in value, but are also almost in phase opposition. Also, due to the fact that in one of the cores the magnetization is proportioned somewhat higher than that of maximum permeability, and in that of the second core somewhat lower than maximum permeability, it follows that satisfactory operation of the transformer is obtained throughout the working range of the current transformer.

The above theoretical considerations have been limited to two cores. However, the Spirakore construction permits the same results to be obtained with a single core by placing some of the turns between the layers of the core spiral.

Performance of "Auxiliary Magnetized" Current Transformer on Overloads

Let us suppose that the primary current increases above the normal value—the flux in the first core increases also, and for a given value of overload, reaches the point of saturation. In the second core (that having an excess of secondary ampere turns), on account of the saturation of the first core, the secondary current increases at a lower rate than the increase in primary current (the flux being the result of the excess secondary ampere turns over the primary ampere turns), decreases, becomes a minimum and starts to increase only when NI_1 becomes larger than I_2N_2. The saturation of the second core is reached for very large values of the primary current. The overload characteristics therefore are quite satisfactory. Figure 22 gives a comparison of the overload characteristics of a 15-kv current transformer with and without compensation. It is noted that the compensation does not appreciably reduce the overload characteristics of the current transformer.

Summary

Recent progress in current-transformer design has been primarily due to the introduction of:

(*a*). Spirakore construction.

1. With lower magnetizing current and losses.
2. With its facility of compensation.

(*b*). Cable type of insulation.

The new transformers are compact, light, and show a considerable reduction in floor space, with accuracy equal to that of previous designs. The compactness of these transformers permits the use of the desirable noninflammable insulation liquid—Pyranol.

Appendix I

Equation 1 can be written:

$$\text{Core 1: } I_1N+I_2\frac{N_1+N_2}{2}-I_2\frac{N_1-N_2}{2}=I_1W_1$$

Similarly, equation 2 can be written:

$$I_1N+I_2\frac{N_1+N_2}{2}-I_2\frac{N_1-N_2}{2}=I_2W_2$$

Obviously the first two terms of the sum are the exciting ampere turns of the ordinary current transformer I_0N; the third term is the ampere turns of "auxiliary magnetization"

$$(I_2W_g),\ \frac{N_1-N_2}{2}$$

being the corresponding number of turns. Figure 21*d* shows the diagram of the ampere turns acting on the current transformer. As can be seen, the components of "premagnetization" cancel each other and take no part in the transformation of the current.

Ultrahigh-Frequency Loop Antennas

ANDREW ALFORD
ASSOCIATE AIEE

A. G. KANDOIAN
NONMEMBER AIEE

ANTENNAS which are discussed in this paper were developed for two applications: (1) to serve as elements in radiating systems of localizers and radio ranges used to guide aircraft; (2) to act as receiving antennas carried by aircraft.

These antennas are in some respects similar to the low-frequency loop antennas and for this reason will be referred to as ultrahigh-frequency loops. The unique property which makes them useful in the above applications is that they radiate only horizontally polarized waves. The directional characteristics of these antennas are similar to those of a vertical dipole except that the waves emitted are horizontally instead of vertically polarized.

Calculation of the Field

Let us consider an antenna system composed of four straight-line radiators, 1, 2, 3, and 4, which are arranged in the form of a square as shown in figure 1.

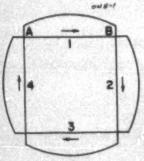

Figure 1. Current distribution in ultrahigh-frequency loop antenna of type I

We shall assume that the currents which flow in radiators 1, 2, 3, and 4 are all in phase and that their directions at any given instant are either as shown by the arrows in figure 1 or reverse. The amplitudes of the currents along each radiator will be assumed to vary sinusoidally with the crest of the current at the center of each radiator.

The electromagnetic field produced by this antenna system at a distant point P may be obtained by adding the fields produced by the individual radiators.

Since the electric and magnetic fields at a distant point are always simply related, so that one may be obtained from the other, it is necessary to calculate only one of them, for example, the magnetic field.

Magnetic Field of One Radiator

The magnetic field due to a linear radiator with a chopped-off sine-wave distribution of figure 1 may be readily calculated by the method described, by one of the authors.[1] In fact, one may assume that the chopped-off sine-wave distribution is the result of two traveling waves proceeding in opposite directions and so timed that the currents are in phase at the center of the element. If the current in one of the two traveling waves is

$$i = i_0 \sin(\omega t - kz) \tag{1}$$

then the current in the other is

$$i' = i_0 \sin(\omega t + kz - lk) \tag{2}$$

The magnetic field due to the first traveling wave is

$$H = \frac{2i_0}{r_1 c}\cot\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1-\cos\theta_1)\right]\times \cos\left[\omega\left(t-\frac{r_A}{c}\right)-\frac{\pi l}{\lambda}(1-\cos\theta_1)\right] \tag{3}$$

while the magnetic field due to the second traveling wave is

$$H' = \frac{2i_0}{rc}\tan\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1+\cos\theta_1)\right]\times \cos\left[\omega\left(t-\frac{r_A}{c}\right)-\frac{\pi l}{\lambda}(1-\cos\theta_1)\right] \tag{4}$$

The total magnetic field is

$$\begin{aligned} H_1 &= H+H' \\ &= \frac{2i_0}{r_1 c}\left\{\tan\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1+\cos\theta_1)\right]+ \cot\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1-\cos\theta_1)\right]\right\}\times \\ &\quad \cos\left[\omega\left(t-\frac{r_A}{c}\right)-\frac{\pi l}{\lambda}(1-\cos\theta_1)\right] \end{aligned} \tag{5}$$

In this equation r_A is the distance between one end A of the radiator and the distant point P; θ_1 is the angle between AP and radiator 1; l is the length of the radiator; c is the velocity of light; λ is the wave-length; $k = 2\pi/\lambda$ and $2i_0$ is the loop current, that is, the current at the center of the radiator.

If in place of r_A we use distance r_1 measured from the center of radiator 1 to point P, then since

$$r_1 = r_A - \frac{\ }{2}\cos\theta_1$$

equation 5 reduces to the following:

$$H_1 = \frac{2i_0}{r_1 c}\left\{\tan\frac{\theta_1}{2}\cdot\sin\left[\frac{\pi l}{\lambda}(1+\cos\theta_1)\right]+ \cot\frac{\theta_1}{2}\cdot\sin\left[\frac{\pi l}{\lambda}(1-\cos\theta_1)\right]\right\}\times \cos\left(\omega t - kr_1 - \frac{\pi l}{\lambda}\right) \tag{6}$$

which shows that the phase of H_1 is the same at all points equidistant from the center of the radiator.

When the length l of the radiator is small in comparison with λ equation 5 reduces to a much simpler form, namely,

$$H_1 = \frac{2i_0}{r_1 c}\left(\frac{2\pi l}{\lambda}\sin\theta_1\right)\cos\left(\omega t - r_1 k - \frac{1}{2}kl\right) \tag{7}$$

While this elementary equation is exact only when l/λ is very small it remains a fair approximation up to $l/\lambda = 1/8$. This may be seen from table I, in which values of H obtained from equations 6 and 7 are given side by side for $l/\lambda = 1/8$ and $l/\lambda = 1/4$.

Magnetic Field of the Loop

The magnetic field produced by the four radiators of the loop antenna is simply a vector sum of the individual fields. That is

$$\boldsymbol{H} = H_1 + H_2 + H_3 + H_4 \tag{8}$$

where H_1, H_2, H_3, H_4 are the magnetic fields as given accurately by equation 6 or approximately by equation 7.

The magnetic vectors H_1 and H_3 due to radiators 1 and 3 are collinear and may be added directly. Similarly vectors H_2 and H_4 may be added directly for the same reason. The resultant (H_1+H_3), however, in general makes an angle with the resultant (H_2+H_4) and this angle depends on the position of point P with respect to the loop, so that it is necessary either to add the two vectorially or to resolve them into mutually perpendicular components and add the latter. This second procedure is preferable and will be followed.

In any case, the first step is to add H_1 and H_3. In accordance with (7)

$$H_1 = \frac{2i_0}{rc}\left(\frac{2\pi l}{\lambda}\sin\theta_1\right)\cos\left(\omega t - r_1 k - \frac{lk}{2}\right) \tag{9}$$

Paper 40-48, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 24, 1939; made available for preprinting January 5, 1940; released for final publication February 16, 1940.

Table I

θ (degrees)		0	10	20	30	40	50	60	70	80	90
$l/\lambda=1/8$	H from equation 6	0.000	0.130	0.252	0.372	0.482	0.577	0.656	0.716	0.750	0.766
	H from equation 5	0.000	0.137	0.270	0.393	0.506	0.602	0.681	0.739	0.774	0.786
$l/\lambda=1/4$	H from equation 5	0.000	0.273	0.536	0.785	1.01	1.20	1.36	1.47	1.54	1.57
	H from equation 6	0.000	0.221	0.436	0.654	0.857	1.039	1.194	1.313	1.386	1.414

$$H_3=\frac{2i_0}{rc}\left(\frac{2\pi l}{\lambda}\sin\theta_3\right)\cos\left(\omega t-r_3k-\frac{lk}{2}\right) \quad (10)$$

From figure 2 it follows, however, that $\theta_1=\theta_3$. r_3 is not equal to r_1, but both may be readily expressed in terms of r_0, the distance from the center of the loop to point P, and θ_3 the angle between element 2 and OP. From figure 2

$r_1=r_0-l/2\cos\theta_3$

$r_3=r_0+l/2\cos\theta_3$

by substituting these values of r_1 and r_3 into (9) and (10), then adding H_1 and H_3 and finally simplifying the result of addition with the aid of the well-known formula

$$\cos A-\cos B=-2\sin\frac{A-B}{2}\sin\frac{A+B}{2}$$

we obtain

$$(H_1+H_3)=\frac{4i_0}{cr}\left(\frac{2\pi l}{\lambda}\sin\theta_1\right)\sin\times$$
$$\left(\frac{\pi l}{\lambda}\cos\theta_3\right)\sin\left(\omega t-kr_0-\frac{lk}{2}\right) \quad (11)$$

Similarly, since

$$(H_2+H_4)=\frac{4i_0}{cr}\left(\frac{2\pi l}{\lambda}\sin\theta_2\right)\times$$
$$\sin\left(\frac{\pi l}{\lambda}\cos\theta_1\right)\sin\left(\omega t-kr_0-\frac{lk}{2}\right) \quad (12)$$

If, in place of approximate equation (7), we had used the exact equation (6), the results would have been the same as (11) and (12), except that in place of $\left(\frac{2\pi l}{\lambda}\sin\theta_1\right)$, we would have

$$\left\{\tan\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1+\cos\theta_1)\right]+\right.$$
$$\left.\cot\frac{\theta_1}{2}\sin\left[\frac{\pi l}{\lambda}(1-\cos\theta_1)\right]\right\}$$

and a similar expression in place of $\left(\frac{2\pi l}{\lambda}\sin\theta_2\right)$.

The resultant vector (H_1+H_3) is at right angles to the plane defined by OP and OB. This vector may be resolved into two mutually perpendicular components, namely H_g directed along the great circle APC and H_s at right angles to this great circle, that is, along the small circle PSQ through P. Both cosine and sine of angle y_1, which vector (H_1+H_3) makes with H_G may be readily found from figure 2. In fact, since (H_1+H_3) is perpendicular to plane OPB it follows that $\angle CPB=x_1=90°-y_1$. From spherical triangle CPB by the rule of sines

$$\frac{\sin x_1}{\sin\alpha}=\frac{\sin 90°}{\sin\theta_1}$$

Hence

$$\sin(90°-y_1)=\cos y_1=\frac{\sin\alpha}{\sin\theta_1}$$

From the same triangle it follows that $\cos\theta_1=\cos\beta\cdot\cos\alpha$. With the aid of this relation $\sin y_1$ may be expressed as follows:

$$\sin y_1=\sqrt{1-\cos^2 y}=\frac{\sqrt{\sin^2\theta_1-\sin^2\alpha}}{\sin\theta_1}$$
$$=\frac{\sqrt{1-\cos^2\beta\sin^2\alpha-(1-\cos^2\alpha)}}{\sin\theta_1}$$
$$=\frac{\cos\alpha\sin\beta}{\sin\theta_1} \quad (13)$$

Therefore,

$$H_{G_{1,3}}=(H_1+H_3)\cos y_1=(H_1+H_3)\frac{\sin\alpha}{\sin\theta_1} \quad (14)$$

and

$$H_{S_{1,3}}=(H_1+H_3)\sin y_1$$
$$=(H_1+H_3)\frac{\cos\alpha\cdot\sin\beta}{\sin\theta_1} \quad (15)$$

Vector (H_2+H_4) is perpendicular to the plane OPD which is defined by OP and the line OD drawn from O, parallel to elements 2 and 4. Angle y_2 which vector (H_2+H_4) makes with meridian APC is equal to $90°-x_2$ where $x_2=\angle CPD$. From right spherical triangle CPD it follows that

$$\frac{\sin x_2}{\sin(90°-\alpha)}=\frac{\sin 90°}{\sin\theta_2}$$

and

$$\cos\theta_2=\cos(90°-\alpha)\cos\beta$$

Hence

$$\cos y_2=\sin x_2=\frac{\cos\alpha}{\sin\theta_2};$$

$$\sin y_2=\frac{\sqrt{\sin^2\theta_2-\cos^2\alpha}}{\sin\theta_2}=\frac{\sin\alpha\cdot\sin\beta}{\sin\theta_2} \quad (16)$$

Thus, the great circle component of (H_2+H_3)

$$H_{G_{2,4}}=(H_2+H_4)\frac{\cos\alpha}{\sin\theta_2} \quad (17)$$

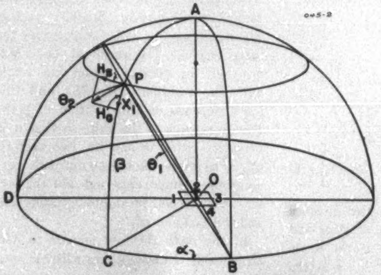
and the small circle component is

$$H_{S_{2,4}}=-(H_2+H_4)\frac{\sin\alpha\cdot\sin\beta}{\sin\theta_2} \quad (18)$$

The negative sign used in the last equation is used to indicate that the small circle component of (H_2+H_4) points to the right when the small circle component of (H_1+H_3) points to the left. Thus, if one of them we call positive, the other has to be negative.

The total great circle component due to the antenna system of figure 1 is thus:

$$H_G=(H_1+H_3)\frac{\sin\alpha}{\sin\theta_1}+(H_2+H_4)\frac{\cos\alpha}{\sin\theta_2} \quad (19)$$



α = CB
β = CP
θ₁ = BP
X₁ = ∠CPB

Values of $H_G\frac{rc}{2i_0}$ from accurate equations 19 and 6 for $l/\lambda=0.25$, $\beta=0$, and variable α

α	0	10	20	30	40	50	60	70	80	90
$H_G\frac{rc}{2i_0}$	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00	2.00

while the small circle component is

$$H_S=(H_1+H_3)\frac{\cos\alpha\sin\beta}{\sin\theta_1}-(H_2+H_4)\frac{\sin\alpha\sin\beta}{\sin\theta_2} \qquad (20)$$

Both of these equations are accurate if the values of H_1, H_2, H_3, and H_4 are calculated from equation 6 and others like it for H_2, H_3, and H_4. When the values of H_1, H_2, H_3, and H_4 are taken from (7) and similar equations for H_2, H_3, H_4, then equations 19 and 20 will be only approximate. Such approximate equations, of course, are very much simpler. By using the approximate values for H_1, H_2, H_3, and H_4 we obtain

$$H_G=\frac{8i_0}{rc}\frac{\pi l}{\lambda}\left[\sin\alpha\cdot\sin\left(\frac{\pi l}{\lambda}\cos\theta_2\right)+\cos\alpha\cdot\sin\left(\frac{\pi l}{\lambda}\cos\theta_2\right)\right] \qquad (21)$$

$$H_S=\frac{8i_0}{rc}\frac{\pi l}{\lambda}\left[\cos\alpha\cdot\sin\beta\cdot\sin\left(\frac{\pi l}{\lambda}\cos\theta_2\right)-\sin\alpha\sin\beta\sin\left(\frac{\pi l}{\lambda}\cos\theta_1\right)\right] \qquad (22)$$

If we again assume that l/λ is small so that

$$\sin\left(\frac{\pi l}{\lambda}\cos\theta_2\right)=\frac{\pi l}{\lambda}\cos\theta_2,$$

$$\sin\left(\frac{\pi l}{\lambda}\cos\theta_1\right)=\frac{\pi l}{\lambda}\cos\theta_1$$

then (21) and (22) reduce to a very simple result which is easy to visualize, namely

$$H_G=\frac{8i_0}{rc}\left(\frac{\pi l}{\lambda}\right)^2\cos\beta \qquad (23)$$

$$H_S=0 \qquad (24)$$

While these equations are exact only when l/λ is very small, they remain reasonably accurate for most purposes even when $l/\lambda={}^1/_8$ and the horizontal characteristic is still substantially circular when $l={}^1/_4\lambda$ as may be seen from table II. A comparison of calculated "vertical characteristic" with measurements is given in figures 2*a* and 2*b*. In these figures the solid curves are calculated from equation 19 using accurate equation 6 for H_1, H_2, H_3, H_4. The measured values are obtained by putting the plane of the loop antenna at right angles to ground and then measuring the resulting horizontal characteristic.

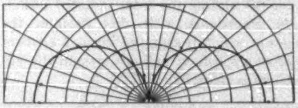

Figure 2a. Vertical characteristic of ultra-high-frequency loop antenna in plane $\alpha=0$ degrees (at right angles to elements 18.3)

Solid curve calculated; points from measurements

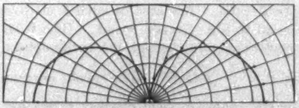

Figure 2b. Vertical characteristic of ultra-high-frequency loop antenna in plane $\alpha=45$ degrees (through diagonal) solid curve calculated; points from measurements

At a distant point from any antenna, the small circle component E_S of the electric field is equal to the great circle component H_G of the magnetic field and the great circle component E_G of the electric field is equal to the small circle component H_S of the magnetic field. Accordingly, in view of (23) and (24)

$$E_G=0 \tag{25}$$

$$E_S=\frac{8i_0}{rc}\left(\frac{\pi l}{\lambda}\right)^2 \cos \beta \tag{26}$$

This result may be stated in more familiar language. Let us suppose that the loop of figure 1 is in a horizontal plane. Then E_S is the horizontal component of the electric field. The great circle component E_G may be resolved into two mutually perpendicular components, one of which is vertical while the other is "longitudinal." Both of these are equal to zero when $E_G=0$, so that the total electric field of the loop antenna may be said to be purely polarized. There is no vertical component present in any direction.

Calculation of Radiation Resistance

Since the efficiency of the ultrahigh-frequency loop antenna depends primarily on the ratio of radiation resistance to the loss resistance of the conductors, it is important to know the value of the radiation resistance of the loop antenna at least approximately. Equation 23 provides us with a very simple and yet reasonably accurate value of the magnetic field at any point in space and permits us to apply the Poynting theorem for calculating the total radiated power. In accordance with this theorem the power which is radiated through element dS of a sphere of radius r around the antenna is given by

$$\frac{c}{8\pi}H^2dS$$

Since field H depends only on β and not on α, we may subdivide the sphere into narrow strips of which width $rd\beta$ included between adjacent small circles, such as for example are defined by $\beta=\beta_1$, and $\beta=\beta_1+d\beta_1$. The area of such a strip is equal to $rd\beta \cdot 2\pi r \cos \beta=dS$. The total power radiated through the entire sphere is $P=\frac{c}{8\pi}\int H^2dS$. The peak current at the center of such element is $2i_0$ and the effective current is $2i_0/\sqrt{2}$. If we define as the radiation resistance of the loop antenna that quantity R which when multiplied by the square of the effective current gives us the total radiated power then

Table III

l/λ	0.05	0.10	0.15	0.20
R	0.194	3.11	15.8	49.8

$$R\left(\frac{2i_0}{\sqrt{2}}\right)^2=P=\frac{c}{8\pi}\int_{-\pi/2}^{+\pi/2}H^2 2\pi r^2 \cos \beta d\beta$$

$$=\frac{16i_0^2}{c}\left(\frac{\pi l}{\lambda}\right)^4\int_{-\pi/2}^{+\pi/2}\cos^3 \beta d\beta$$

$$=\frac{64}{3c}i_0^2\left(\frac{\pi l}{\lambda}\right)^4$$

and hence

$$R=320\left(\frac{\pi l}{\lambda}\right)^4 \text{ ohms} \tag{27}$$

Table III shows how R varies with l/λ.

Equation 27 gives values of R which are too large, and this error increases with l/λ. The difficulty, lies in the fact that equation 23 used in deriving (27) gives too large a value of H for the greater values of l/λ as may be seen from table II. When more accurate values of radiation resistance are desired it is necessary to calculate R by numerical integration using (6) in place of (7) for H_1. A fair approximation is obtained from the following semiempirical equation

$$R=320\left(\sin \frac{\pi l}{\lambda}\right)^4 \tag{27a}$$

Equation 27 is a special case of a more general result which holds for loops of rectangular shapes and probably for loops of any shape, namely

$$R=320\left(\frac{\sqrt{A}}{\lambda}\right)^4 \tag{28}$$[*]

where A is the area of the loop. This more general equation like (27) is also subject to the condition that l/λ is small.

Before closing the subject of radiation resistance of loop antennas, it may be of interest to note that if several loop antennas (for example N) were superposed and connected in some manner so that they were in series and yet the currents were in phase, then each antenna would produce a field H and total field produced by all working together would be NH and the power radiated would be proportional to N^2H^2. It follows that the radiation resistance of a loop antenna made of N turns of wire is N^2 times that of a single-turn loop, that is

$$R_N=320N^2\left(\frac{\pi\sqrt{A}}{\lambda}\right)^4 \text{ ohms}$$

Design of Ultrahigh-Frequency Loop Antennas

In practice the current distribution illustrated in figure 1 may be obtained by the use of the circuit illustrated in figure 3. In this arrangement, portions BB', DD', AC of conductors 1, 2, 3, and 4 are very close to each other, so that radiations from them cancel, and the effective current distribution, so far as radiation is concerned, is as in figure 1.

The impedance looking into terminals (K, K') of network of figure 3 is usually largely reactive and is thus not well suited for being fed directly by a shielded transmission line. In order to secure a more convenient input impedance an ultrahigh-frequency loop antenna is usually provided with what may be called a *resonant transmission line*. This feature is illustrated in figure 3 $K, K'-T$.

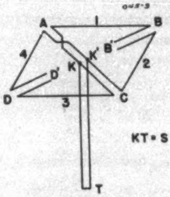

Figure 3. Ultrahigh-frequency loop antenna of type I

The optimum design of the resonant transmission line, as well as the design of the radiators themselves depends on factors which are seldom considered. For this reason, some of the details will be described.

First, we shall discuss the design of the resonant line. For a given field at a distant point it is necessary to maintain a certain value of current in the radiators. In turn, this value of current in the radiators corresponds to a certain fixed value of voltage across the terminals (K, K') of the resonant line. The power lost in this resonant line depends primarily on the current which flows in it and on the conductors which have to carry this current. It may be readily shown that the "loop current" I which flows through short-circuited end T of a transmission line section of lengths (see figure 3) when the voltage is V at its terminals is given by the following relation:

$$I=\frac{V}{Z_0 \sin \frac{2\pi s}{\lambda}}$$

---

[*] Equation for H for a rectangular loop may be derived by the same method used to obtain H for the square loop. Incidentally the field of a small rectangular loop is circular.

The power which is lost in the section of line is therefore

$$P = R \cdot \frac{V^2}{\left(Z_0 \sin \frac{2\pi s}{\lambda}\right)^2}$$

From this equation it may be readily seen that in order that the losses may be kept at a minimum, it is desirable

1. To keep V which corresponds to a given current in the radiators as low as possible.
2. To make R as low as possible and
3. To keep Z_0 as high as possible.

Voltage V for a given current in the radiators can be kept down by using conductors of low surge impedance, that is, by making the radiators of wide strips of metal. The second and third requirements have to be met by making R/Z_0^2 a minimum, because the two quantities R and Z_0 are mutually interrelated. It may be pointed out that the requirement that R/Z_0^2 be a minimum is different from the usual requirement that "attenuation" in a matched line be a minimum because the latter requirement demands that R/Z_0 and not R/Z_0^2 be a minimum. Thus, for example, in case of a coaxial line the requirement that R/Z_0 be minimum leads to the well-known ratio of a diameter of the outer to the inner conductors be around 3.8 while the requirement that R/Z_0^2 be minimum results in an optimum ratio around 9.0.

While the proportions of the conductor used in the "resonant line" are not critical, the controlling relations must be kept in mind if an efficient design is to be achieved, particularly when the dimensions of the loop antenna and hence its radiation resistance are relatively small.

Measurement of Radiation Resistance

The radiation resistance of a loop antenna may be measured by several different methods.

Method 1. The loop antenna is placed in the field of another radiator (for example, a half wave) which is a number of wave lengths away. One of the radiators of the loop antenna is cut in two as to its center, and the circuit is completed by means of a half wave length of transmission line as illustrated in figure 4. The complete circuit is resonated by moving short-circuiting bar T of the "resonant line" of the loop. The current which is induced in the loop antenna is measured by a very sensitive receiver M so designed that it does not couple in any appreciable resistance into the loop circuit. This freedom from coupled-in resistance may be established by using another control receiver or very sensitive meter M' while varying the coupling between receiver M and the loop.

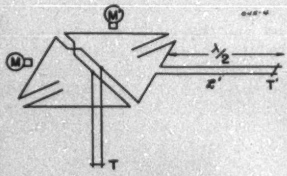

Figure 4. Method 1

Receiver M must be calibrated against a linear current meter so that the reading may be translated into relative values of current.

The measurements consist of introducing known amounts of reactance in series with one of the radiators of the loop by moving short-circuiting bar T' of half-wave line L and measuring the corresponding decrease in current in the radiators by means of receiver M. The result of such measurements is a resonance curve from which the total resistance, that is, the radiation resistance plus loss resistance can be calculated.

In order to separate the radiator resistance from the loss resistance the radiators of the loop are replaced by others of similar construction, but which are bent in such a way that the area of the loop is decreased to negligible size so that the radiation resistance practically vanishes. Then another resonance curve is obtained from which the loss resistance can be calculated.

Method 2. One of the radiators of the loop antenna is cut as in method 1, but the gap bridged by a short piece of wire W which is used as a shunt for measuring current. The loop antenna placed in the field of another radiator as in method 1 is resonated by means of short-circuiting bar T of the resonant line, and current I_W in wire W is compared with current I_T in short-circuiting bar T. Then short-circuiting bar T is translated by known amounts and a resonance curve is obtained. The resistance R_T which is calculated from this curve is not the sum R_W of radiation resistance plus loss resistance but is a resistance seen at short-circuiting bar T if the latter were out. The two resistances, however, are quite simply related because the dissipated power must be equal to

$I_T^2 R_T$ as well as to $I_W^2 R_W$

so that

$$I_T^2 R_T = I_W^2 R_W$$

and

$$R_W = R_T \frac{I_T^2}{I_W^2}$$

Since the ratio of these two currents is measured, the value of R_W can be calculated from R_T.

Method 3. The loop antenna is supplied with power in the normal way by a transmission line L which is very nearly matched so that the ratio of maximum to minimum of current in the standing waves is very nearly unity. The power which is supplied to the antenna can then be accurately measured by measuring the maximum and minimum currents or voltages along the transmission line. This delivered power is

$$P = Z_0 i_{\max} \cdot i_{\min}$$

where Z_0 is surge impedance of the transmission line. Current I_n which this known power produces in the radiator of the loop antenna is also measured. Then the total resistance R_W of the antenna (that is, radiation resistance + loss resistance) is calculated from the following equation.

$$RI_n^2 = Z_0\, i_{\max} \cdot i_{\min}$$

In order to separate the radiation resistance from the loss resistance, the radiators of the loop are then bent so as to reduce the radiation resistance to a negligible value and the process is repeated, this time yielding only the loss resistance.

All three of these methods plus separate measurements of resistance of the resonant line were used to check the radia-

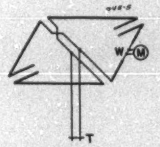

Figure 5. Method 2

tion calculated from equation 27. The results of some of these measurements are summarized in table IV.

Table IV

Method 1	23 ohms
Method 2	20 ohms
Theory, equation 27	44 ohms
Theory, equation 27*a*	35 ohms

Frequency used 109.9 megacycles.

Loop Antennas of Types II and III

It is sometimes desirable to make a loop antenna as compact and as simple as possible. Under such circumstances the design illustrated in figure 7 may be adopted. The loop antenna of figure 7 has a current distribution which results in somewhat greater radiation in direction *AA'* than in direction *BB'*. This deviation from a circular pattern, however, is rather small when the antenna dimensions are small in comparison with (12) as is usually the case. Antennas of this design will be referred to as ultrahigh-frequency loop antennas of type II.

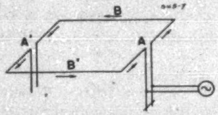

Figure 7. Ultrahigh-frequency loop antenna of type II

The loop antenna of figure 8 is probably the simplest one of all loop antennas. The main difficulty with this type of loop is that when this antenna is made large enough to have sufficient radiation resistance to be efficient, the current distribution becomes quite asymmetric, with most of the current in radiator 2 and little current in radiator 4. This current distribution results in maximum radiation in direction *CC* and some vertically polarized radiation in directions other than *CC'*. Such antennas will be referred to as ultrahigh-frequency loop antennas of type III.

Gain of Loop Antennas and Radiation Efficiency

Since the field pattern of a small loop antenna is identical except for polarization with that of a small dipole, it is manifest that for the same amount of input power, the fields at a distant point should be equal. The difference, if any, will be due to losses in associated feeding arrangements.

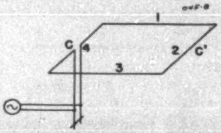

Figure 8. Ultrahigh-frequency loop antenna of type III

The loop antennas of type I with radiation resistance around 25 ohms, if carefully designed, have radiation efficiencies somewhat greater than 95 per cent.

A direct comparison of the fields produced by a loop of type I and a horizontal half wave when the two were fed with exactly the same power showed that the fields were very nearly equal with a slight preference (about one-fourth decibel) for the field due to the loop.

With the smaller loop antenna having radiation resistances of the order of five ohms, the radiation efficiency is naturally below 95 per cent because the loss resistance of the associated resonant circuit is usually of the order of one or two ohms.

In general, the radiation efficiency is equal to

$$\eta = \frac{\text{radiation resistance}}{\text{radiation resistance} + \text{loss resistance}}$$

When the radiation resistance is greater than loss resistance, the efficiency is high, but when it is less than the loss resistance, the efficiency is low. When the radiation resistance is low, the radiation efficiency is proportional to the radiation resistance.

Applications of Loop Antennas of the Three Types

Ultrahigh-frequency antennas of type I illustrated in figures 3 and 9, because of their higher efficiency, are particularly well suited for use as transmitting antennas. Thus, for example, an array of these antennas may be used as the radiating system of a localizer for guiding aircraft to an airport.

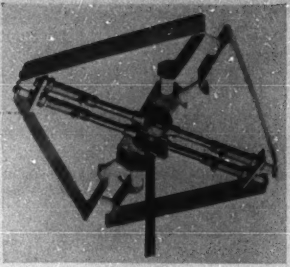

Figure 9. Ultrahigh-frequency loop antenna of type I

Figure 10. Ultrahigh-frequency loop antenna of type II installed on a transport plane

Antennas of type II are particularly well adapted for use as receiving antennas carried by aircraft.

These antennas consist of fewer parts and are therefore lighter than antennas of type I. When installed on aircraft about two feet above the fuselage, their direction characteristics in the horizontal plane are nearly circular which is exactly what is desired in such applications.

Figure 10 illustrates an experimental antenna of this type installed on a Douglas transport plane.

Antennas of type III are best suited for use in portable instruments such as, for example, field-exploring devices.

Ultrahigh-frequency loop antennas can be built for frequencies of the order of ten megacycles. At these frequencies the loop antennas make excellent "omnidirectional" horizontally polarized standard antennas for measuring gain of horizontally polarized directional arrays.

Historical and General Observations

THE most important problem in flying today is that of landing a plane under adverse weather conditions. A modern transport plane can take off and fly to the vicinity of its destination through nearly any type of weather by means of modern methods of air navigation. The use of the radio range together with flight and navigation instruments has made this possible. However, it is extremely hazardous to land aircraft with standard equipment under conditions of low ceiling and poor visibility. This limitation is the reason for the majority of flight cancellations of scheduled air transport.

Under poor weather conditions when landing is permitted by present regulations the difficulties in landing are still acute. It usually takes a plane as much as 15 or 20 minutes to make a landing at a busy airport after being cleared to land by the airport traffic control tower. Concurrently, other planes will arrive at the cone of silence over the range station and will have to circle at various altitudes above the radio range and each await its turn to land. Thus it is possible that a plane may have to wait an hour or more before it is able to make a landing. When there is little fuel left, the problem becomes even more critical.

Various methods of instrument landing have been attempted; however, the most promising method is one which utilizes radio waves. These waves are used to give lateral guidance, vertical guidance, and position fixes. With the aid of such a system the entire process of radio instrument landing would take from four to five minutes. This would help to reduce the traffic congestion at an air terminal and avoid delay in landing.

If air transportation is to compete with other established modes of transportation, it must continue its safety record and at the same time increase the regularity of scheduled flight operations. This can best be done by the adoption of a standard reliable instrument landing system.

The Civil Aeronautics Authority, realizing this to be the bottleneck of safe flying under conditions of low ceiling and poor visibility, has endeavored to overcome this difficulty by fostering the development of a suitable instrument landing system. In May 1938, bids were issued on specifications covering the development of a system which would comply with the rigid requirements of airline service. The specifications were based on the development of the art of instrument landing prior to this date.

Development of Instrument Landing

The history of the development of instrument landing dates back approximately ten years. The first serious work on instrument landing was done by the Bureau of Standards for the Aeronautics Branch of the Department of Commerce in 1928. This system used a visual radio range beacon as a runway localizer and marker beacons located on the course to inform the pilot of his location with respect to the point of landing. The altitude was controlled by means of a barometric altimeter. Using this system without the markers, Lieutenant J. H. Doolittle of the Daniel Guggenheim fund made the first successful instrument landing in history on September 24, 1929, at Mitchell Field.

In 1929, Diamond and Dunmore of the Bureau of Standards proposed a method providing guidance in the vertical plane using a constant-intensity glide path. This, along with the runway localizer, gave a three-dimensional system. The runway localizer operated on 278 kilocycles and utilized small multiturn loops. The glide path operated on 90.8 megacycles and utilized a horizontally polarized array. The marker beacons used long low transmission line antennas operating on 3,105 kilocycles. Installations were made at College Park in 1931; at Newark, N. J., in 1933; and Oakland, Calif., in 1934. The Newark and Oakland installations used two marker beacons, one at the airport boundary and one along the line of approach, some distance out from the airport. The system was designed to simplify the interpretation of the radio signals by the pilot. A single cross-pointer instrument provided visual runway-localizer and landing-beam course indications and distinctive modulation of the approach and boundary marker beacons was employed. On March 20, 1933, a completely blind flight was made from College Park to Newark (except for a slight break over Baltimore), on a day when the weather grounded all other aircraft on the Atlantic seaboard. Altogether over 100 blind landings were made at Newark.

Test flights of the Newark installation indicated the practicability of the fundamental principles of the system and pointed toward further development. Reduction of cost of ground station equipment, elimination of bends in the localizer course due to presence of railroad tracks, power lines, etc., and increased slope of the landing path were desired. Since the localizer course is more susceptible to bending at low frequencies, it was decided to use ultrahigh frequencies for the runway localizer as well as the glide path. Tests were made on a combined runway localizer and landing beam operating on a single ultrahigh frequency. Further study indicated that horizontal polarization was preferable for the glide path.

In 1933, the Airways Division of the Department of Commerce installed an instrument landing system using the conventional aural-type radio range augmented by a radio marker and a sensitive Kollsman altimeter on the plane. The plane is guided over the radio range cone of silence which is approximately two miles from the field at a specified altitude, and from this point the pilot glides along the radio range course and over the marker to the field at a rate of descent of 400 feet per minute. This system was not considered feasible as an instrument landing system since the ac-

Paper 40-43, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 24, 1939; made available for preprinting December 28, 1939; released for final publication March 29, 1940.

W. E. Jackson is chief of the radio development section, Civil Aeronautics Authority, Washington, D. C.; A. Alford and P. F. Byrne are with the International Telephone Development Company, New York, N. Y., and H. B. Fischer is with Bell Telephone Laboratories, New York.

curacy of the barometric altimeter is not great enough to prevent the possibility of undershooting or overshooting the airport. However, this is the system which is used at present for coming into airports under low ceilings.

In 1932 and 1933, the Army Air Corps at Wright Field developed and tested a system utilizing a radio compass for guidance and a sensitive altimeter for checking the altitude over ultrahigh-frequency markers. Although installations were begun at a number of airports throughout the United States, it was abandoned since a majority of the airlines felt that it did not give sufficiently precise indications for safe commercial use. Its disadvantages were that a barometric altimeter cannot be relied upon and that a heading established by radio compass is subject to error when cross winds are present. The major advantage was that the system was simple to fly and required a relatively short pilot-training period.

In 1935, the Washington Institute of Technology completed an instrument landing system with elements similar to those of the original Bureau of Standards system. The ground equipment, except the marker beacon, was mounted in an automobile trailer to permit the operation of the system in any direction. The glide-path transmitter operated at a frequency of approximately 93 megacycles, its antenna array utilizing horizontal polarization. The localizer operated on 278 kilocycles and transmitted into small multiturn loops, keying I in one loop and A in the other. The A-I visual indication method was discarded in favor of a double modulator type of localizer; that is, modulating one loop at 65 cycles and the other at 86.7 cycles. Originally, two separate power amplifiers were used, each of which was modulated at one of the two frequencies mentioned above. Each power amplifier independently excited one of the loops. Any change of output in either amplifier caused localizer course variations. To overcome this difficulty, a single power supply was used, and a mechanical modulator connected to the output of the tank circuit was used to supply each of the loops, one at 65 cycles and the other at 86.7 cycles. Thus, any change in amplifier output varied both patterns and the course alignment was not affected. This system was found to work quite effectively. The major disadvantage with this and all other systems using relatively low radio frequencies for the runway localizer is that bends and multiple courses may be obtained when operated in the vicinity of transmission lines, railroad tracks, mountains, and broken terrain.

Transcontinental and Western Air, Inc., in 1935 developed a combination glide path and localizer unit at the Kansas City airport using a frequency of 85 megacycles. Considerable difficulty was encountered due to variations in the glide path when crossing over a river. It was not until later that it was determined that vertically polarized waves were responsible for the discontinuity.

In 1935, the Bureau of Air Commerce conducted further tests on several modifications of the basic Bureau of Standards system. It was decided to abandon keying systems for course identification in favor of a double-modulation system, using 65 cycles in one loop and 86.7 cycles in the other, giving a visual indication. Later it was found that bent and multiple courses which prevailed at the low frequencies could be eliminated by the use of an ultrahigh-frequency localizer, provided care was exercised in locating the localizer with respect to reflecting objects such as hangars, gas tanks, towers, and buildings.

In 1934 and 1935, Doctor E. Kramar of the Lorenz Company in Germany developed a blind landing system using the same elements originally used by the Bureau of Standards, that is, glide path, runway localizer, marker beacons, and monitor system. The transmitter was operated on 33.3 megacycles and excited a vertical half-wave radiator. On each side of the vertical radiator, a reflector was located with a relay at its center. One reflector was keyed by dots and the other with dashes. By interlocking the dots and dashes, two elliptical patterns were obtained, producing an equisignal zone which gave two courses. A visual indicator was obtained by means of a rectifier circuit and amplifier. However, the indicator gave a kicking needle indication. The glide path was obtained by following a constant-field-intensity path. The outer marker was located about 1.9 miles from the airport and the inner marker about 0.19 mile from the airport. Each of the markers transmitted on 38 megacycles, the outer marker modulated at 700 cycles and keyed with dashes $^{4}/_{10}$ second long, and the inner marker modulated at 1,700 cycles and keyed with dots $^{1}/_{18}$ second long. Each marker gave an aural indication as well as lighting an individual light on the instrument panel. A complete monitoring apparatus was provided.

Through the courtesy of the International Telephone and Telegraph Corporation, one complete set of equipment was installed at the Indianapolis airport for test purposes. These tests indicated that approaches could be made to the field under conditions of poor visibility and low ceilings with good reliability. However, several limitations to this system were found. The radio range could be flown better aurally than visually. Originally, the course was about six degrees broad, the width desired in Europe. The pilots in this country who flew this equipment felt that the courses were too wide. The course was reduced to two degrees but even further reduction was desired.

Another difficulty observed was the fact that the glide path was smooth down to a point just beyond the end of the runway, at which point the glide path took a definite dive into the ground. The reinforcing steel in the runway was probably the cause for this abrupt change in the glide path. It was later determined that the use of horizontally polarized waves instead of vertically polarized waves could be used to eliminate this difficulty.

The frequencies used, namely 33.3 and 38 megacycles, are not believed satisfactory for a system which would be used universally, since reflection from the Heaviside layer would occasionally cause interference between stations several thousand miles apart. The Lorenz system, however, had the advantage that the entire system operated on ultrahigh frequencies which were free from atmospheric disturbances.

In 1936 and 1937, United Air Lines and the Bendix Corporation constructed and tested a system having the same elements as the Bureau of Standards system using a combined glide path and localizer transmitter operating on 91 megacycles. Horizontally polarized waves were utilized and to avoid directional effects, a horizontal loop which had a nondirectional characteristic was used for the receiving antenna. An automatic pilot was occasionally utilized in making instrument landings. This enabled the pilot to concentrate on the indications of the cross-pointer instrument and follow them more accurately. During 1936 and 1937 approximately 3,000 hooded landings were made on this system.

It is evident that a considerable fund of knowledge has been gained from the numerous systems which have been described. Many notable contributions have been made by Lorenz, the Washington Institute of Technology, Bendix, United Air Lines, Transcontinental and Western Air, Inc., and the various Government agencies which have worked on the problem. Each of the systems has its limitations although some are better than others for making instrument landings consistently under service conditions.

It was desired to set up specifications which could be used as the basis of a standard instrument landing system for installation on a national scale. The use of ultrahigh frequencies was felt desirable not only because of its freedom from atmospheric and interstation interference, but because the present overcrowding of the low-frequency spectrum makes it impossible to procure frequencies for use in instrument landing on a national scale. This is in accordance with the general plan of the CAA eventually to operate the majority of air navigation aids on the ultrahigh frequencies.

Recommendations of the Radio Technical Committee for Aeronautics

The matter was considered on December 17, 1937, at the sixth meeting of the Radio Technical Committee for Aeronautics, which is a co-ordinating group to recommend policies in regard to radio development as applied to aeronautics. The Radio Technical Committee for Aeronautics is made up of representatives from the airlines, manufacturers, and various Government agencies. The Radio Technical Committee for Aeronautics subcommittee on instrument landing made the following recommendations which are quoted here.

1. Runway Localizer

(*a*). The runway localizer shall operate on an ultra-high frequency, preferably in the band 92–96 megacycles, or, if the localizer transmitter is operated as a separate unit, in the band 108–112 megacycles.

(*b*). Straight course, i.e., one which has no bends or multiple courses perceptible to a pilot flying in still air.

(*c*). The difference in the magnitude of the two patterns of the localizer shall be 0.5 decibel at 1.5 degrees either side of the center line as measured with a linear detector.

(*d*). The vertical needle of the cross-pointer indicator shall give a 10-degree deflection indication for a 1.9-degree angular deviation from the center line of the runway.

(*e*). The range of use as a runway localizer should be 20 miles at 3,000 feet.

(*f*). Freedom from interference pattern effects perceptible to the pilot both in elevation and azimuth.

2. Glide Path

(*a*). The glide path shall operate on an ultra-high frequency, preferably in the band 92–96 megacycles.

(*b*). A smooth glide path shall be provided, i.e., one which is free from interference pattern effects perceptible to the pilot when on the localizer course.

(*c*). The system shall be capable of adjustment to provide a suitable glide path.

3. Markers

(*a*). The markers shall operate on 75 megacycles.

(*b*). It shall be possible to positively identify each marker both aurally and visually by modulation and keying. Modulation frequency of the inner marker shall be 1,300 cycles and that of the outer marker shall be 400 cycles.

(*c*). A normal arrangement of markers would be:

1. At the normal intersection with the glide path.
2. Near the boundary of the airport, the exact location to be determined by local conditions.

(*d*). The marker beacons shall have an array adjustable so that when installed in the boundary position the beam will cause useful indications of a visual device within 700 feet either side of the on-course path and for 300 feet along the glide-path trajectory. Indications from this marker shall be receivable to an altitude of 2,000 feet.

(*e*). The outer markers shall have sufficient power to accomplish a similar visual indication with the same beam pattern at 2,000 feet.

4. Monitor System

(*a*). Satisfactory means for indicating visually the operation of all equipment, shall be provided at a central point.

(*b*). Whatever form of visual indication may be employed shall be smooth in performance and have no irregular characteristics.

5. General Characteristics

(*a*). Frequency of emission of all of the elements of the system shall be equivalent to that obtained with a low-temperature-coefficient quartz crystal.

(*b*). The number of fixed or portable equipment required will depend on conditions prevailing at individual airports.

(*c*). The installation of the foregoing equipment shall not constitute an obstruction to a normal approach to a runway.

6. The installation of the best known type of approach and runway lights appears to be a most desirable measure in combination with instrument landing facilities.

These are the basic recommendations which were used by the Bureau of Air Commerce in preparing specifications for the development of an instrument landing system. The Bureau of Air Commerce advertised bids and in June 1938 awarded a contract to International Telephone Development Company, Inc., to carry on this development. The complete experimental landing system provides facilities for landing in four directions. The equipment was installed at Indianapolis and was accepted by the Civil Aeronautics Authority in October 1939.

Indianapolis Instrument Landing Installation

Airport Facilities

Four complete groups of instrument landing transmitters have been installed at the Indianapolis Municipal Airport permitting landings in any of four wind directions; northeast, southeast, southwest, and northwest (see figure 1). Each landing direction requires the installation of four separate transmitters; localizer, glide path, inner marker, and outer marker. Each of these installations is connected to the airport control tower by telephone lines so that the group of four transmitters for any of the landing directions can be turned on to meet local wind conditions.

Figure 1. Indianapolis airport and instrument landing layout

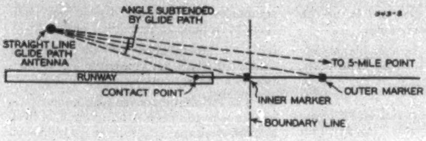

Figure 2. Location of straight-line glide path array

At the outset of the airport installations, the plans called for four installations of constant-intensity glide paths of parabolic shape. This is a well-known type of path obtained by using a simple antenna with, preferably, a broad radiation pattern. The transmitter and radiators may be placed either off the end of the runway or to the side of the runway but the latter position, if opposite or slightly forward from the far end of the runway, will usually place the contact point at a more favorable location near the beginning of the runway and give the ship a longer space in which to land and roll to a stop.

Glide-Path Development

Before these installations were complete, however, a system for producing a glide path of the constant-intensity type which is substantially straight from the outer marker to the point of contact, had been developed and in order to test the new type of path an installation was made at Indianapolis in place of one of the parabolic-glide-path installations.

Previous to the time of this test installation, belief had been expressed by a number of authorities on the subject that a straight-line glide path, as described above, would be ideal because it could be flown with a constant throttle setting and because the path would clear local obstacles with a greater margin. After a number of flight tests by competent pilots including airline pilots, it developed that a path of this shape had too great a rate of descent at the contact point causing the ship to land excessively hard, which, if adopted, would cause the passengers considerable alarm and discomfort. After these and subsequent tests, it developed that the ideal shape for a glide path would be a substantially straight line from a point 1,500 feet at five miles from the airport to the airport boundary, from where the path would become slightly parabolic in shape intersecting the runway surface at approximately one degree. The path would pass over the outer marker, two miles from the airport boundary, between 500 and 700 feet elevation. A path of approximately this shape has since been produced at Indianapolis.

The method by which constant-intensity paths of various shapes, including the straight line and improved arrangements, have been produced involves locating the glide-path antennas at a considerable distance to one side of the runway and forward along the runway so that the various points along the glide path appear in different directions as viewed from the glide-path antenna as shown in figure 2. In this way, the angle subtended by the glide path, as viewed from the glide-path antenna, is opened up so that it becomes possible, by making the antenna directive in the horizontal plane, to proportion the radiation along the extent of the glide path and control the height of the path at the various points. Thus, for example, by sending less energy toward the outer marker the glide path may be made higher there and by sending more energy toward the five-mile point, the path may be lowered at this point.

In figure 3 is illustrated the antenna system which produced an approximately straight-line glide path from the outer marker to the point of contact. This system consisted of two ultrahigh-frequency loop antennas spaced approximately one wave-length apart, fed 180 degrees out of phase with unequal amounts of energy and located in front of a reflecting screen. The antenna system which produces the more suitable type of path involves the use of a greater number of elements to produce the required field pattern shape.

The installation for the "straight line" glide path is located 1,350 feet off the center line of the runway and 1,050 feet forward from the end. The parabolic-curve glide path installations are located 400 feet off the center of the runway and approximately opposite the far end of the runway.

Localizer Installation

The localizer installation consists of a wooden building approximately 12 feet square located off the end of the runway and a localizer monitor unit situated about 100 feet in front of the building on a line with the runway (see figure 4). Inside the building are the localizer antennas mounted under and close to the apex of the roof, the localizer transmitter, the modulator unit, the voltage regulator, the service switches, and telephone (see figure 5). A large wire screen is placed horizontally across the inside of the building just below the antennas primarily to minimize the radio-frequency field in the lower part of the building, in order to avoid induction of currents in and

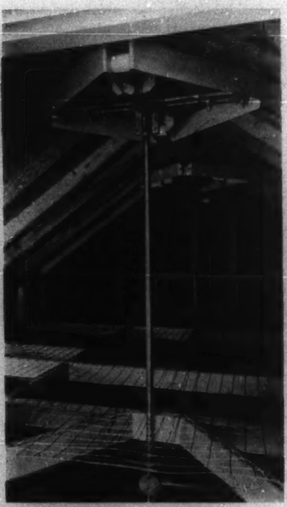
consequent reradiation from the irregular objects below the screen. The transmitter and modulator units are mounted on the floor underneath the wire netting.

Localizer Antennas

Early work has shown that fewer common objects around an airport reflect horizontally polarized waves to the same extent as vertically polarized waves. Consequently, it is to be expected that, in general, cleaner patterns can be obtained with horizontally polarized waves than with vertically polarized waves. This point has been strikingly demonstrated at Indianapolis by making direct comparison between two localizers placed in the same location and having identical radiation patterns, the only difference being that one was horizontally polarized and the other vertically polarized. Both of these patterns were fairly broad so that radiation was sent out to various surrounding objects which could reradiate and superimpose their reradiated fields onto the primary field. As a result of the addition of these fields bends appeared in the course. The amplitude of the bends was considerably greater with vertically polarized radiation than with horizontally polarized radiation. In addition, recordings made of the field radiated in other directions lead to the same conclusions.

Figure 6. Localizer array of ultrahigh-frequency loop antennas



These tests showed that a greater number of objects in the field were more effectively reflecting the vertically polarized waves than the horizontal waves. These objects included a hangar, a power line, several buildings, a group of trees, and several fences. While it is of course possible to find objects, for example horizontal wires, which will reflect horizontally polarized waves more effectively than vertically polarized waves, the fact remains that fewer of the common objects which are confronted in practice reflect the horizontally polarized wave to the same extent that they reflect the vertically polarized waves.

In addition to the use of horizontal polarization, it is very important to use pure polarization. If both vertical and horizontal components are present it is possible with certain arrangements of the plane's receiving antenna that either the main course appears displaced from its true location or, which is even worse, a new apparent course is obtained which would not be present if the antenna were operating properly. This situation might arise if the receiving antenna were injured or improperly installed. It is apparent that the presence of vertical components with the horizontal components may actually be dangerous.

In addition to this, the presence of vertical components leads to an effect which has been referred to as "pushing" of the course. This is noticed when the ship is maneuvering to locate the course. The apparent course appears to be displaced depending on the orientation of the ship and when the pilot attempts to turn into the course, he finds that it has disappeared. This effect, under some conditions, may amount to pushing the course as much as one mile off the true course at a distance of ten miles from the localizer while with pure polarization, this effect does not appear.

In order to realize the advantages of horizontal polarization, a special antenna element was developed primarily for localizer use which radiates pure horizontally polarized waves in all directions. The field pattern in the horizontal plane is circular and in the vertical a figure of eight with zero radiation upward. This element is known as the ultrahigh-frequency loop antenna, three of which are shown in figure 6 mounted under the roof of a localizer house. When these loop antennas are used in the localizer antenna system, the maximum vertical component throughout the entire field pattern does not exceed 5 per cent of the horizontal component at that point.

By using three of these elements arranged in line at right angles to the axis of the runway, it is possible to obtain a two-course radio range with patterns similar to those illustrated in figure 7. The course attained will be relatively broad and there will be a substantial amount of radiation directed toward surrounding objects. While this pattern is suitable for relatively clear locations and would be excellent for use as a radio-range pattern where the antenna is located well above surrounding objects,

Figure 7. Ultrahigh-frequency field patterns from localizer antenna

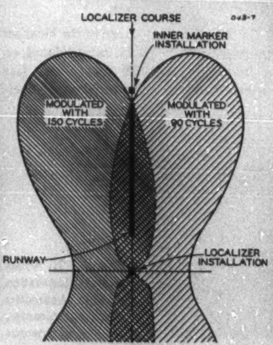


Figure 8. Interior of localizer transmitter from rear

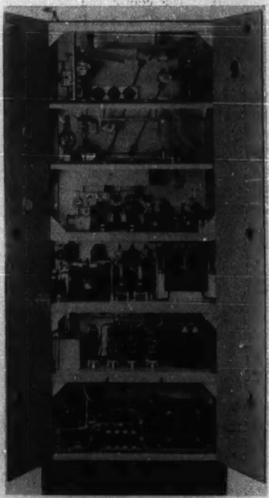

such a pattern may not be entirely satisfactory in an airport in the presence of hangars, buildings, and other reflecting objects. For this application, a pattern which results in much sharper courses and much less off course radiation is desirable in order to secure freedom from course irregularities. In order to produce a more suitable pattern, more radiators are required. Radiating systems with five, six, and seven elements have been used at Indianapolis and a localizer building with a five-element array is shown in figure 4. The fourth and fifth elements, placed in line with the center three, are located in the extensions built onto the ends of the buildings. These extra elements are parasitically driven.

With the antenna systems outlined above, the courses produced at Indianapolis are entirely free of multiple courses and the bends in any of the courses do not exceed 0.15 degree and these bends could be further reduced if not completely eliminated by the results of more recent localizer development work. However, since these bends are so small that they are barely perceptible on the cross-pointer instrument, further improvement is not warranted. Experience has shown that unless bends exceed 0.18 degree or more in amplitude, they are not objectionable.

The two overlapping patterns in the radiated field give side indications of the guiding path which may be easily located at distances of 20 miles from the airport boundary. The course can be picked up at a distance of 70 miles from the airport while flying at an elevation of 4,000 feet or over.

The four localizers installed at Indianapolis have various degrees of sharpness; the sharpness being the ratio in decibels of the field strength of the 90-cycle and the 150-cycle patterns at $1^1/_2$ degrees off course. The sharpest of the patterns exceeds six decibels while others range in the neighborhood of two decibels.

The courses are straight and reliably stable; maintaining their alignment to within one-tenth of one degree under all normal weather conditions.

Localizer Modulator

The localizer modulator is a mechanical modulator constructed to furnish modulated radio-frequency energy for the two overlapping localizer field patterns (see figure 7). Inasmuch as the position of the localizer course is largely dependent on the relative amplitude of the two field patterns, the mechanical type of modulator is used because of its inherent stability and freedom from aging such as would be found in vacuum-tube modulators. The modulator divides the output of the localizer transmitter equally, modulating one-half of the power at a 90-cycle rate and the other half at a 150-cycle rate. Bridge networks, built into the modulator, divide the transmitter output and prevent cross talk or interaction between the 90- and 150-cycle modulator sections as well as feed the carrier and side bands with proper amplitude and phase to the three main localizer antenna radiators. Controls are provided in the unit for adjusting the position of the course with respect to the runway.

The normal percentage of modulation obtained with the mechanical modulator ranges between 95 and 100 per cent although any percentage below this range may be obtained. The radio-frequency-modulated envelope shape from either the 90 or the 150 modulator section, independently, is such that the audio-frequency distortion as measured in the output of a nondistorting detector does not exceed ten per cent and normally ranges close to six per cent. Cross modulation between channels does not exceed four per cent; this percentage being the per cent of 150-cycle modulation appearing in the 90-cycle channel or the per cent of 90-cycle modulation in the 150-cycle channel.

Localizer Transmitter

The rated power output of the localizer transmitter is 300 watts, unmodulated, on a frequency of 109.9 megacycles (see figures 5 and 8). The transmitter operates from 220 volts, single phase, 60 cycles, and receives its entire power of approximately 2,000 watts through a voltage regulator which holds the voltage within plus or minus one per cent for all normal feeder variations.

Figure 10. Marker transmitter

The transmitter is crystal controlled from a 4,579.17-kilocycle temperature-controlled crystal and the crystal oscillator tube functions also as a frequency multiplier. Three frequency multiplier stages follow the crystal oscillator tube to produce the output operating frequency. In order to raise the output of the final multiplier to the rated transmitter output level, the last two stages are push-pull amplifiers operating on the output frequency.

In order to insure reliable operation of the transmitter during cold weather, the ventilating and modulator motors are electrically heated to maintain their bearing temperature above the freezing point. Special lubricating oils which remain viscous to very low temperatures are used in the bearings of contactors and other mechanical parts. The circuit-breaker dash pot also contains a special fluid which remains viscous down to the low temperatures in which this unattended equipment will be required to operate.

The transmitter contains control relays so that it can be operated from the tower. A monitoring arrangement is provided which operates in conjunction with the field monitor (to be described below) so that the position of the course with respect to the runway as well as the strength of the radiated patterns may be ascertained from meters located on the front of the transmitter.

Localizer Monitor

In order to monitor the operation of the localizer installation, from the control tower, a "localizer monitor" is installed about 100 feet from the localizer building on a line between the latter and the end of the runway as shown in figure 4. The monitor contains an insensitive receiver

Figure 9. Inner-marker installation showing transmitter house, counterpoise, and antennas

Figure 11. Monitor and control desk in airport control tower

which operates a course indicating instrument in the localizer transmitter and a duplicate instrument in the control-tower desk. The indication is the same as would be obtained from the vertical needle in the cross-pointer instrument of an airplane were it stationed at the monitor site. The monitor facilities are adjusted to indicate the extent of off course deviation in fractions of one degree.

Underground Localizer Installation

In one localizer installation where insufficient space was available off the end of the runway, making it necessary to locate the building close to the runway, the equipment was installed in a concrete pit below ground level to lower the building height and reduce the hazard. The floor of the pit is approximately eight feet below ground level and accommodates the same equipment as the normal building with the addition of the high-voltage distribution transformer. The pit is covered by a wooden structure shaped like the roof of the normal localizer building. Under the roof are the localizer antennas situated about six feet above ground level (see figure 6). The only additional equipment required for this installation is a sump pump to protect against the possibility of water gathering in the pit.

The lowering of the antenna system close to the ground in this installation in no way affected the operation of the localizer except that the distance from the airport at which the course could be picked up was somewhat reduced.

Glide-Path Installation

There are two types of glide-path installations at Indianapolis; the installation for producing a parabolic path and the installation for producing a straight-line path. In both installations, the transmitter is located inside a wooden building approximately the same size as the localizer house. The antennas for the straight-line installation are erected outside the building as shown in figure 3 while the antennas for the parabolic installation are erected inside the building. The antennas for the latter installation consist of two half-wave radiators fed in phase and mounted horizontally end to end along one wall about ten feet above the floor. A vertical wire screen the length of the building and extending from the roof to about five feet above the floor is located one-quarter wave length behind the antennas. The building is so oriented that the maximum of radiation is directed toward the approach end of the runway served by the installation.

Glide-Path Transmitter

The glide-path transmitter is identical in construction and size to the localizer transmitter except that it operates on a frequency of 93.9 megacycles; requires a crystal with a frequency of 3,912.5 kilocycles; the output is modulated at 60 cycles and no monitoring facilities for use with a field monitor are required. The 60-cycle modulation is accomplished by applying 60-cycle plate voltage to the two tubes in parallel in the output stage. Means for adjusting this voltage are provided in the transmitter so that the field strength along the constant-intensity path can be adjusted. In general, the field strength for all constant-intensity paths must be identical at a given height over the outer markers.

Marker Installation

Marker beacon installations consist, mainly, of a small waterproof aluminum house situated alongside of a wire screen counterpoise 20 feet square, over the center of which is located two half-wave radiators mounted end to end (see figure 9.) The waterproof house is approximately $3^1/_2$ feet long, $2^1/_2$ feet wide, and 3 feet high with a sloping roof, mounted above ground on angle legs. The wire screen is supported by an angle framework and also mounted above ground on angle legs. Concentric gas-filled transmission lines joining the waterproof house with a matching box located between the ends of the radiators, are used for feeding the marker transmitter output to the radiators.

The marker transmitter and its associated line-voltage regulator along with a telephone box and cable terminal are mounted inside the waterproof house. The transmitter is mounted on a sliding shelf so that it can be easily pulled out of the small house for servicing while in operation. While in this position, complete access may be had to all parts of the transmitter.

The installation is oriented so that the end-on radiators are parallel to the center line of the runway. In this way, the major axis of the elliptically shaped pattern in the horizontal plane is at right angles and situated over the runway center line. In outer-marker installations, the radiators are located one-quarter wave length over the counterpoise whereas the radiators in

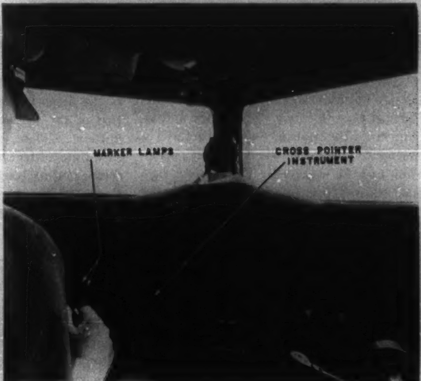

Figure 12. Airplane instrument panel showing cross-pointer instrument and marker lights

the inner marker installation are only one-eighth wave length above the counterpoise. In the latter installation, where the equipment is located close to the end of the runway, the maximum over-all height of any piece of equipment does not exceed four feet.

MARKER TRANSMITTERS

The marker transmitters are approximately 18 inches high, 27 inches wide, and 15 inches deep (see figure 10). The transmitter is built as a single portable unit, containing all radio-frequency and power-supply circuits, audio oscillator and modulator, keying and monitoring equipment. All electrical connections are made to the transmitter through easily removed plugs. The rated output of the transmitter is five watts on 75 megacycles and the carrier frequency is stabilized by a crystal on 4,166.7 kilocycles.

In the radio-frequency-stage lineup, the crystal oscillator tube serves as a frequency multiplier in addition to its duty as an oscillator. Following the oscillator stage are two frequency-multiplier stages and one amplifier stage operating on carrier frequency. The radio-frequency carrier in the outer marker transmitter is modulated with 400 cycles keyed so as to produce equal-length pulses at the rate of two per second. The inner marker carrier is modulated with 1,300 cycles and keyed so as to produce equal-length pulses at the rate of six per second. Keying of the modulating voltage is accomplished with electrical contacts mounted on a small electric motor located within the transmitter. The motor operates on a low direct potential and requires a relatively small amount of power from the d-c plate-supply source. The motor is especially designed and constructed for reliable operation in the extreme temperature ranges of minus 40 to plus 75 degrees centigrade in which the marker equipment is required to operate.

The transmitters are intended for remote operation and monitoring from the airport control tower. A monitor unit is built into the transmitter which returns a signal to the tower where correct operation may be observed. The monitor signal returns over one pair of telephone wires which also carries direct current for controlling the transmitter as well as voice and ringing frequencies for telephone service between tower and marker.

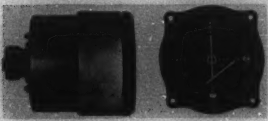

Figure 13. Cross-pointer instrument

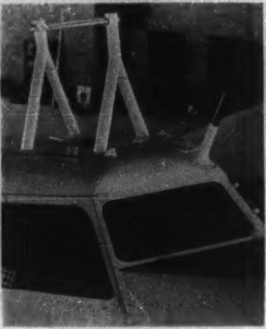

Figure 14. Ultrahigh-frequency loop antenna for reception of localizer and glide-path indications mounted on top of ship

EQUIPMENT CONTROL

The airport tower is equipped with a monitor and control desk by which the tower operator can select landing directions at will (see figure 11). Calibrated instruments and signal lamps give quantitative and qualitative indications of the various transmitters. These indicators are operated by the transmitter monitors and field monitors and indicate the position of the glide path, alignment of the runway localizer courses, and correct operation of the marker transmitters. If the output of any transmitter falls below a predetermined level, visual and aural alarms indicate the trouble. The alarms also operate if the runway localizer course should shift sufficiently to cause an airplane following the course to land off the runway.

The top of the desk is a pictorial map of the airport showing clearly the position of the various runways and transmitters. Colored signal lamps represent each transmitter and are lighted when the corresponding transmitters are in operation. At the head of each runway is located a translucent miniature airplane which is lighted to show the direction of approach.

A pen recorder incorporated in the unit supplies a permanent record of the operation of the system. This instrument records the elapsed time a runway has been in operation, the output of each transmitter, and the localizer course alignment. This multiple function is accomplished with a single pen by recording successive short intervals of the operation of each unit.

Telephone wires emanating from this desk and terminating at the field installations provide means for starting and stopping the equipment as well as monitoring the operation of the equipment. Telephone-type cables were laid on the airport property to provide wire connections between the control tower and the localizer installations, glide-path installations, and the inner-marker installations. Telephone lines from the control tower to the outer marker positions are provided by the local telephone company.

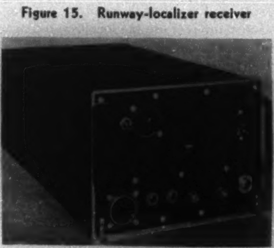
The outer markers, which operate from the 115-volt mains, receive their power from the local power company mains closest to the installation site. Power for operation of the localizer, glide-path, and inner-marker equipment is fed from the control tower at 2,300 volts in high-voltage cables also laid on the airport property.

Airplane Instrument-Landing Receiving Equipment

AIRPLANE FACILITIES

In order to utilize the various signals sent by the transmitters on the ground the pilot observes the position of the two needles of a cross-pointer meter and also notes when either of two marker indicator lamps is illuminated. A view of a typical airplane instrument panel showing the location of the meter and the lights is shown in figure 12 while a view of the cross-pointer meter is shown in figure 13. The two needles of the meter are operated by the outputs of two special radio receivers which receive the transmissions from the glide path and the runway localizer transmitters. Three indicator lights are operated from the output of the marker beacon receiver. Two of these are used in connection with the instrument landing system and show when the plane is over the outer marker and the in-

Figure 15. Runway-localizer receiver



ner marker. The other light shows the pilot when he is over one of the fan markers located at important points along the airway or over the towers of the radio-range transmitting station which are equipped with cone-of-silence markers. The marker-beacon receiver is in continuous operation during the course of a flight as it has other important uses in addition to its part in the instrument-landing procedure while the glide-path and the localizer receiver are used only while making an instrument landing.

One antenna, shown in figure 14, is used to receive both the runway-localizer and the glide-path signals. This antenna is of the horizontal ultrahigh-frequency loop type tuned to 93.9 and 109.9 megacycles and is designed to receive horizontally polarized waves. As mounted on a plane it has an essentially circular horizontal reception pattern. A horizontal dipole antenna mounted underneath the plane is used to receive the marker-beacon signals.

In common with all receivers designed for use in airplanes the receivers for this service must be compact, lightweight, and rugged. In addition to these basic requirements the demands of this new service impose a very rigorous requirement for stability of operation. In spite of wide variations in ambient temperature, humidity, and primary power-supply voltage, the characteristics of the receivers must remain substantially constant as any variation during the landing maneuver will result in an apparent change in the path. The principal characteristics of these three receivers are described in the following sections.

Runway-Localizer Receiver

This receiver, a front view of which is shown in figure 15, employs a superheterodyne circuit and has a crystal-controlled beating oscillator for operation at a fixed frequency of 109.9 megacycles. As explained in a previous section of this paper the runway-localizer transmitter is continuously modulated with 90-cycle and 150-cycle tones. In order to insure that there is no apparent error in the course, it is essential that the relative gain for these two modulation frequencies remains constant.

A simplified schematic of the circuit arrangement is shown in figure 16. The radio-frequency input is applied to the control grid of the first detector $V1$ while the beating-oscillator voltage is impressed on the screen grid. The output of the tube is fed to a three-stage intermediate-frequency amplifier system operating at a frequency of ten megacycles and having four inductively coupled double-tuned circuits. These highly selective circuits in connection with the tuned input circuit provide the radio-frequency selectivity shown in figure 17. The output of the intermediate-frequency system is fed to diode $D1$ of the detector tube $V5$ and the audio-frequency voltage developed across the diode load resistance $R1$ is impressed upon the grid of the triode section of this tube. The amplified audio-frequency output appearing across the cathode resistance $R2$ is applied to the grid of the second audio-frequency amplifier tube $V6$. The plate of this tube is connected to the double-band-pass audio-frequency filter which separates the 90-cycle and the 150-cycle components of the signal modulation. Two copper-oxide rectifiers containing selected and balanced units are used to rectify the two audio voltages for operating the vertical needle of the cross-pointer meter. In order to compensate for any unbalance which exists in the audio-frequency filter due to temperature variation, a temperature-sensitive resistance element $RT1$ having a high negative temperature coefficient is connected across one of the rectifier load resistors.

Signals received from the localizer transmitter vary over a wide range of intensity as the plane approaches the airport and therefore a wide-range automatic-volume-control system is required to maintain a nearly constant audio output. The control grids of the intermediate-frequency amplifier tubes $V2$ and $V3$ obtain their normal minimum bias from the drop across resistance $R3$ and the gain adjusting potentiometer $P1$. When a signal is received, the automatic-volume-control circuit increases the bias applied to the control grids in proportion to the signal level applied to the receiver. An increase in signal results in an increased negative bias on the grid of $V5$ which reduces the plate current of the triode section flowing through the cathode load resistance $R2$. The voltage drop across the resistance is reduced and the potential of the cathode of $V5$ is lowered until it becomes more negative than the normal bias applied to diode plate $D2$ of the $V5$. At that point diode $D2$ draws current which flows through $R4$ and the voltage drop across that resistor is added to the normal bias to secure automatic volume control on the grids of $V2$ and $V3$. Bridged across the minimum-bias resistor is another temperature-sensitive element $RT2$ which causes the bias voltage appearing across $R4$ to decrease with increasing ambient temperature in order to maintain nearly constant receiver gain.

Glide-Path Receiver

This receiver, which is quite similar in appearance to the localizer receiver, is a crystal-controlled superheterodyne set operating at a fixed frequency of 93.9 megacycles, intended for the reception of tone-modulated continuous-wave transmission from the glide-path transmitter located at the airport. It is essential that the over-all receiver gain remain practically constant for a wide range of variation of temperature, battery voltage, and

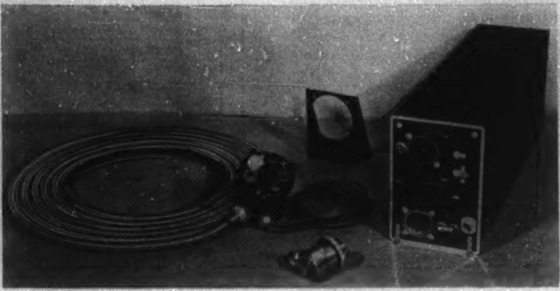

Figure 18. Marker-beacon receiver

humidity as the determination of the path of descent of the airplane is based upon a fixed receiver sensitivity. In order to meet these requirements, voltage regulators, ballast lamps, and temperature-sensitive resistance elements are used within the unit.

Marker-Beacon Receiver

This receiver, a photograph of which is shown in figure 18, is a crystal-controlled superheterodyne unit operating on a fixed frequency of 75 megacycles and arranged to provide both visual and aural indication of the signal being received.

Visual indications are provided by three indicator lamps mounted on the ship's instrument panel. As previously pointed out, two of the lamps are used for instrument landing purposes and the third is used to indicate the position of fan markers and cone-of-silence markers. The modulation frequency for the latter is 3,000 cycles; the inner and outer markers employ 1,300 and 400 cycles respectively.

Three filters are provided in the receiver to separate the 400-, 1,300-, and 3,000-cycle modulating tones. The output of each filter is applied to a copper-oxide rectifier and the resulting current flows through a d-c winding on a saturable-core reactor. An a-c winding also on this core is in series with the indicating lamp and the lamp-voltage supply source. When the impedance of the reactor is lowered by saturation due to the direct current, sufficient alternating current flows to operate the lamp.

Results

After the equipment was installed a meeting of the Radio Technical Committee for Aeronautics was held at Indianapolis in September 1939, for the purpose of demonstrating the equipment to the members and to determine if the system developed was suitable for airline use. The committee unanimously agreed that the general Radio Technical Committee for Aeronautics specifications had been complied with fully. However, in view of the improvement in the glide path which was demonstrated as being entirely feasible, the airline pilots present felt that neither a straight line nor a curved glide path was entirely satisfactory and made the following recommendations as to the most desirable shape of the glide path when on the localizer course:

> "A glide path intersection shall be obtained at 1,500 feet altitude at a distance of six miles from the transmitter end of the runway. The point of contact shall be not closer than 3,000 feet from the far end of the runway. At the point of contact the glide path shall have an angle with the runway not less than one degree and not more than two degrees. The glide path shall pass through the following points not less than 500 feet nor more than 700 feet altitude at a distance of three miles from far end of runway, and 1,500 feet altitude at six miles. The rate of descent shall not exceed 800 feet per minute."

Further work has been conducted by the International Telephone Development Company, which has succeeded in demonstrating a glide path meeting the pilots' recommendations.

Approximately 50 hooded landings have been made in various types of aircraft such as Douglas *DC*-3, Boeing 247, and Waco *N*. Numerous instrument approaches have been made under conditions of heavy rain, snow, low ceilings, and poor visibility. A program of flight training and testing is being organized in order that the airlines, army, and navy may flight test the equipment either under the hood or under bad weather conditions.

The Civil Aeronautics Authority is planning to install a number of similar systems throughout the United States in the near future for service tests and pilot training.

Conclusions

1. To effect precise landings with a minimum of effort on the pilot, experience has shown that four separate elements are advantageous, a localizer to furnish lateral guidance, a glide path to provide the path of descent, and two markers to indicate the progress along the course determined by the localizer and glide path.

2. Ultrashort waves may be successfully employed to provide both horizontal and vertical guidance as well as marker indications.

3. Localizer courses must be much sharper than heretofore employed to avoid mutilation by reflections. The difference in amplitude of the patterns should be at least 2.2 decibels $1^1/_2$ degrees off course in the majority of installations. This is approximately four times sharper than stipulated in specifications of the Radio Technical Committee for Aeronautics. In some instances it is necessary to have a sharpness as great as 6 decibels in order to eliminate bends in the course.

4. Localizer polarization must be pure to secure independence of the aircraft antenna characteristics and direction of approach of the plane to the localizer course.

5. The localizer should be independent from the glide path in order to permit its installation well beyond the end of the runway so that it is not a hazard to aircraft landing or taking off.

6. Experience has indicated that the two-course localizer is inherently more simple to use than localizers with four or more courses.

7. It is advantageous for the glide path to be of a controllable type so that path shape can be adjusted during installation to accommodate the landing characteristics of aircraft.

THE PROBLEM of developing an instrument landing system in which the pilot is kept informed as to both his location and orientation by the indications of a single instrument was put to the Massachusetts Institute of Technology several years ago by I. R. Metcalf of the Civil Aeronautics Authority. The solution of this problem includes the application of centimeter waves, the development of a straight-line glide path, and the realization of a novel instrument combination. Intrinsically and because of recent trends in aircraft navigation these features, we believe, represent significant advances in the art. The experimental development described here in general outline was carried on under the sponsorship of the Authority and was built on MIT's background of research on the broad problem of navigation in fog and on work in the short-wave field per se as a foundation.[1] The apparatus was designed to demonstrate feasibility only. Commercial embodiment of the results is it is felt now within reach of the industry.

The General Problem

The problem as presented was based on the idea that a serviceable instrument landing system could be realized if, under conditions of no visibility, it were possible to present to the pilot the same information he would obtain were he to land on a clear night by means of three lights arranged on the landing field as shown in figure 1. These lights would indicate to the pilot in a simple, natural, and continuous manner not only his location but also his attitude and heading.

To visualize the problem in greater detail imagine the three lights as seen through a transparent screen in front of the pilot. Assume that the screen has vertical and horizontal cross hairs intersecting at its center. When the airplane is in the proper orientation for landing, and is on the reference landing path defined by the three lights as shown, the pilot sees these lights equally spaced along the horizontal cross hair, the center light coinciding with the center of the screen. Any departure of the lights from this pattern on the screen indicates a corresponding departure of the airplane from the proper location or orientation.

In the simplest interpretation, the location of the light group indicates orientation and the relative configuration of the lights as a group indicates location. Thus turning of the airplane to the right or left moves the lights as a group left or right respectively; moving to the right or left of the reference landing path moves the image of the center light nearer to the image of the right- or left-hand light respectively.*

The Metcalf problem then was to provide on the instrument panel of an airplane the same information indirectly by means of the visual image of three hypothetical lights with movements corresponding to those of the real light arrangement under corresponding conditions. The solution MIT proposed was to synthesize the image of the three hypothetical lights by a combination of radio- and gyro-instrument means. Information regarding orientation was to be derived from gyro instruments on the airplane, and information regarding location to be derived from electromagnetic radiation from transmitting means on the ground. The combined information was in turn to control three spots on the face of a cathode-ray tube used as the indicating instrument. This use of the gyro group suggested at once an instrument that could serve not only for landing but also for cross-country flying.

The radiation from the ground was to define a straight-line reference path down which the airplane could be flown at its normal glide angle. It is easier to control an airplane when landing at constant air speed and rate of descent, that is, when flying down a straight glide path than when following a curved glide path. Hence, aside from the fact that a straight-line path is inherent to the three-light landing procedure, from flying considerations alone, there is justification for a path of this form. The information must be given to the airplane as to whether it is above, below, to the right, or to the left of the reference path. It was planned to supply this information by the use of crossed or equisignal beams: one pair with separate modulations for the up-down information and a corresponding pair for the right-left information. Utilization of the equisignal beams made available the advantages of automatic volume control, including freedom from effects of change of received signal with antenna orientation, and of change in receiver sensitivity.

To the location information obtained from equisignal beams and the orientation information from the gyroscopic instruments† must be added distance information. Distance information, if it is desired to complete the three-light illusion, could be obtained from a signal intensity control moving the two outer spots on the indicating instrument farther apart as the landing field is approached, or it could be given independently by means of marker beacons.

The research resolved itself into two principal aspects, one dealing with the production of the instrument in the air-

* During the study and testing of various approximations to the true image of the three lights on the landing field, the fact developed that the pilot, when landing in clear weather, makes use of the horizon as well as the view of the airport in front of him. It is possible to give the equivalent of this information by controlling the relative vertical positions of the outer two of the three spots on the instrument by means of the gyro-horizon alone and the center one by means of the landing reference path alone. The general behavior of the three spots will still conform to the basic principles set forth in the original problem.

† The heading information, it was contemplated, could also be obtained from a radio compass.

plane and the other with the production of the landing reference path. The rigid self-imposed requirement that this path should be substantially free from extraneous effects indicated concentrated beams and this in turn made it desirable to use as short a wave length as possible for beam energy. On the other hand the limitations of high-frequency commercial vacuum-tube equipment made it desirable initially to set 100 centimeters as the lower practical limit of this wave length. Although this wave length was much longer than desirable, it was hoped that as the research progressed the ultrahigh-frequency art would develop to a stage where generators and receivers of much shorter wave length would be available. In the experimental investigation wave lengths of the order of 50 centimeters were used for convenience with the idea that the data could subsequently be applied to the design of longer or shorter wave length radiators by the use of dimensional multiplication. Later promising developments in the art made it feasible to adhere to approximately 50-centimeter waves in all our work.

The possibility of using infrared radiation as well as radio waves to produce the reference path was also investigated. The MIT work on light penetration of fog had indicated that there was possibly a pass region in the spectrum between 8 and 12 microns. This possibility together with the feeling on the part of many that infrared waves offered a solution made it important to examine the applicability of infrared radiation. After investigation including experimental confirmation covering wave lengths out to 15 microns, the use of these long infrared waves was ruled out because of the unobtainable power that would be required to provide the desired range over a sufficiently wide field for this specific purpose.‡

The Instrument

The instrument aspect of the problem very quickly reduced itself to three divisions: the obtaining of electrical signals from the gyro instruments, the development of instrumental means of synthesizing the images of the three hypothetical lights for presentation to the pilot, and the study of approximations to the true image patterns that might be utilized as practical variations or simplifications.

A simple electrical take-off for obtaining signals from the gyroscopic instruments was sought and it was decided to investigate first the applicability of a voltage divider or slide-wire means whereby rotation of the gyro element would cause a fine wire brush to move across a resistor card and deliver a voltage of magnitude and sign proportional to angular displacement. Should this idea prove workable it promised direct control of the spots and a simple means of controlling instrument sensitivity by the adjustment of the direct voltage across the dividers. It also offered the possibility of grading these resistors so as to make possible sensitivity which varied with angular displacement.

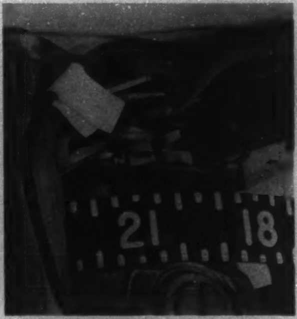

Figure 2. Electrical take-off mechanism in one of the gyro units

In taking off electrical control voltages from the gyro instruments it is essential that friction and other disturbing forces be kept low, if the gyros are to function properly. The bank and climb gyro is stabilized by gravity, and will eventually return to its proper orientation if displaced, but the directional gyro has nothing but its "memory" to rely on, once it has been oriented. Therefore, the very practical criterion that the frictional and other forces added by the electrical take-off mechanism be small compared to the friction already existing in the gyro mounting, was used as a guide in this work. Doctor C. S. Draper of the MIT department of aeronautics was fortunately able to provide not only the necessary information about commercial gyro instruments, but also the means for measuring the added friction of the electrical take-off. The development of the electrical take-off was carried out largely under his direction by his colleague Doctor J. D. Trimmer. On the basis of their work the simple expedient of obtaining voltages directly from a resistor by a contact brush carried on the gyro mounting ring appeared to be practical. The added friction amounted to about ten per cent of that already in the gyro and produced no detectable effect on the behavior of the instrument. A photograph of the electrical take-off in one of the gyro units is shown in figure 2.

Since the voltage delivered by the gyro instrument was sufficient to deflect the spots on the cathode-ray tube directly, amplifiers with their attendant complexity were unnecessary. As negligible currents were required, the area of contact could be kept very small and contact pressures kept sufficiently high to make the resistor card self-cleaning without producing undue drag. The brushes were shaped from tungsten wire 0.003 inch diameter.

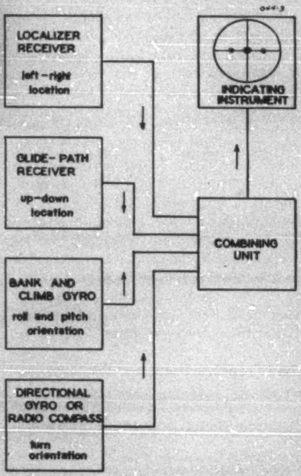

Figure 3. Block diagram of airplane equipment

Instead of a three-gun cathode-ray tube, which might at first thought appear to be ideally suited to produce the three-light pattern, a standard tube was used in conjunction with mechanical commutation** to produce the three-gun effect. The control circuit was somewhat simpler and it was also a definite advantage to have only one spot to be focused and centered as well as to have the same sensitivity for each virtual spot. Furthermore, a wide variety of single-gun tubes were readily available.

---

‡ The work of MIT in the general field of light scattering by fog, including the work done in connection with the instrument landing project, will be published in the near future.

** Electronic commutation was examined; however mechanical commutation was more readily adaptable to this particular instrument.

These elements were combined as shown in the block diagram of figure 3 which summarizes the broad features of the instrument and indicates their functional interrelationship.

Thus, a method and mechanism have been developed for synthesizing a visual image simulating three lights on the landing field. This system, like any other which makes use of electrically operated indicating instruments, makes possible the removal of the gyro instruments from the instrument panel, the duplication or repetition of their indication at several locations in the airplane, and the concentration of essential landing information on a single instrument. The use of the equipment during flight is also feasible. The instrument gives gyro information and the runway localizer signals may be replaced by range signals.

Finally the instrument indication is not limited to the three-spot image but can, for instance, be in the form of a central figure moved by the reference path or by the radio range signals and a bar image, simulating the bar on the gyro horizon. The bar image can also be controlled in translation so as to convey not only bank and climb information but also heading. A bar-and-circle pattern has been incorporated in the Flightray[2] developed by the Sperry Gyroscope Company, Inc.*

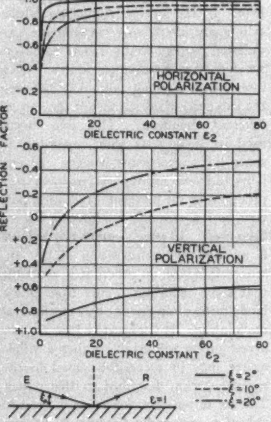

Figure 4. Reflection factor for ultrahigh-frequency waves as a function of dielectric constant

Figure 5. Electromagnetic horn radiator

The Landing Reference Path

A straight-line landing reference path with an adjustable angle of from three to six degrees with respect to the horizontal was desired. It was recognized at the outset that to realize this path relatively free from ground, weather, and reflection effects highly directive component beams would be required. This would be particularly true for the lower of the two beams making up the glide path. To fulfill this requirement by radio means called for wave lengths as short as possible in order to obviate radiating systems of undue physical size. A comparative investigation was therefore made of broadside and end-fire arrays of half-wave elements, long-wire antennas, parabolic reflectors, and horn radiators.

Preliminary analysis and tests indicated that a horn of rectangular cross section could by appropriate design be made to produce smooth beams of the requisite degree of directivity in horizontal and vertical planes.[3] On the basis of the results of this investigation the horn type of radiator was selected because it was simpler to adjust, freer from spurious radiation from feed wires, and had inherently a better radiation pattern than was obtainable from the other devices examined.

Even with wave lengths as short as 50 centimeters and antennas of reasonable size, it is not possible to produce landing beams of sufficient sharpness to be entirely free from the effects of reflected energy from the ground. It was therefore desirable to determine which of the two polarizations, horizontal or vertical, would make these reflections least. Past experiments with instrument landing systems had resulted in a divided opinion as to the preference of one polarization over the other for this service. A theoretical investigation of this problem was therefore carried out to aid in selecting proper polarization. The earth may be treated with a fair degree of accuracy as a perfect dielectric for the ultrahigh frequencies employed in this system. Its effect may be expressed by means of a reflection factor, equal to the ratio of the intensity of the wave reflected from it to that incident upon it. A change in the physical condition of the earth caused by rain, drought, sleet, and snow is accompanied by a change of the dielectric constant. That polarization will be preferable which causes the least change in reflection factor for given changes in the dielectric constant. A typical set of curves showing the variation of the reflection factor with the dielectric constant for several angles of incidence is reproduced in figure 4. Clearly, horizontal polarization provides the more uniform behavior with changing ground conditions. Since making this study, confirmatory experimental evidence from several sources has been obtained in favor of horizontal polarization of beams for instrument landing.

Making use of a theory of horn design evolved in a separate research program[4] a horn was constructed specifically for the production of a landing beam. The body of the horn was made of three-eighth-inch bakelite-bonded plywood and was lined inside with thin copper foil. Figure 5 shows the completed horn. It is about

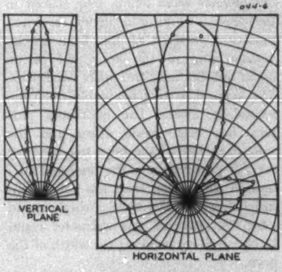

Figure 6. Measured relative electric intensity in vertical and horizontal planes for the horn of figure 5

---

* The Sperry Gyroscope Company at about the time the MIT program was developed undertook the development of a cathode-ray-tube flight instrument which included information from the gyro group. It is with pleasure that we acknowledge here the cordial constructive exchange of ideas with this organization in connection with related aspects of our project.

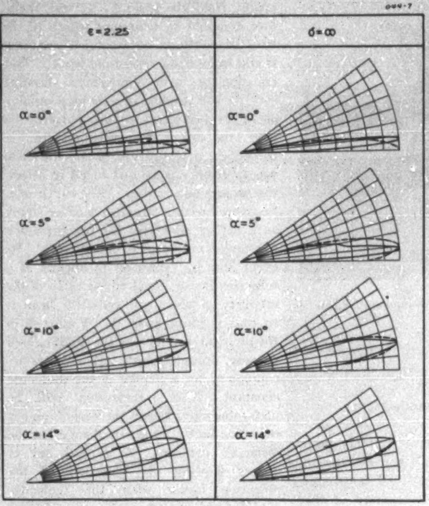

Figure 7. Calculated effects of a perfect dielectric earth ($\epsilon = 2.25$) and a perfectly conducting earth ($\sigma = \infty$), on horizontally polarized radiation from the horn of figure 5. Axis of horn inclined at the angle α; mouth resting on the earth

26 feet long by 10 feet high by 2.5 feet wide (at the mouth) and has an angle of flare of 20 degrees in the direction of height. At a wave length of 50 centimeters this corresponds to a height of 6 wave lengths and a width of 1.5 wave lengths. The theoretical power gain compared to a Hertzian doublet is 50. The exciting antenna is a straight wire about one-quarter wave length long placed in the throat. Figure 6 shows measured radiation patterns of this horn in the vertical and in the horizontal planes under substantially free-space conditions. The vertical pattern is notably free from secondary lobes. The horizontal pattern has been made sharp and the secondary lobes have been tolerated for sake of power gain. The preferred pattern in this plane, were less power gain satisfactory, would have a single broad lobe. A beam of this character could be obtained by reducing the width of the horn.

The next step was to determine the best position of the horn with respect to the ground for the production of a landing beam. Patterns were therefore calculated for different heights of the horn above ground, for different angles of the axis of the horn with the horizontal, for perfect dielectric and perfectly conducting earths, for horizontal and for vertical polarizations, and for different sizes of horns. Examples of these patterns are shown in figure 7. Measurements of radiation patterns were made with the aid of captive balloons. These measurements agreed well with the theoretical predictions. From these calculations and measurements it appeared that the disposition of two identical horns for the glide path beams might be as follows: the lower edges of the mouths of both horns touch the ground, with one horn at an angle of elevation of five degrees, and the other at an angle of ten degrees. With this disposition, additional sharpness of the lower beam is obtained at present by helpfully utilizing the reflections from the ground. When transmitting with equal strength, these two horns should yield a glide path angle of about six degrees; a smaller angle could be obtained by reducing the power output or the modulation of the lower horn. A pair of horns of the type shown in figure 5 was set up in the field in accordance with this information. These radiators were fed from separate triode oscillators operating at slightly different frequencies and modulated at 90 and 150 cycles per second respectively. Balloon measurements of the resultant equisignal straight-line glide path were then made over a distance of 700 feet with highly satisfactory results as indicated in figure 8. Its angle with the ground was adjustable at will to values between 6 and 11 degrees by adjusting the relative sensitivities of the 90- and 150-cycles-per-second audio channels of the receiver.

Excitation of Beam Radiators

In the equisignal beam tests separate transmitters operating at slightly different carrier frequencies were used to excite the two horn radiators in order to avoid space interference of the carriers and to obviate any difficulty of cross modulation. Cross modulation would cause a broadening of the on-course or equisignal zone. Cross modulation through a common power source could be avoided by the use of buffer amplifiers, or by a bridge connection[5] of the two output lines to a single power source. Numerous tests have established that there is no appreciable mutual impedance effect between the horn antennas employed here. In the absence of phase modulation, space interference between the two radiated carriers occurs if both radiators are fed from a common source. Such interference does not take place between the two pairs of side bands for they are of different frequency. The two horns used in these tests were separated in space by several wave lengths. Strong lobes and zeros might therefore have been produced in the horizontal radiation pattern had a common modulation source been used. In some systems this trouble is avoided by juxtaposition of the antennas in space; in others it is probable that some reduction occurs from phase modulation introduced by mechanical modulation. It is expected that further investigation will establish that a single source may be successfully used in the specific system described in this paper. The use of separate oscillators is open to objection principally because it doubles the transmitting apparatus.

For most of the experimental investigations carried on during this research,

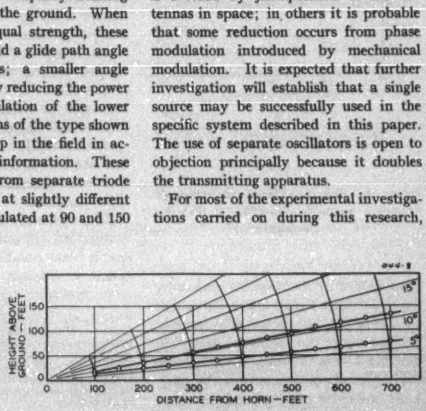

Figure 8. Balloon measurements of equi-signal paths. The two paths correspond to different adjustments of the audio channels of the receiver

simple low-powered oscillators[6] were employed as sources. These oscillators used the Western Electric 316-*A* triode in a feedback circuit with short-circuited coaxial transmission lines as circuit elements. They operated at wave lengths from several meters down to the limit of oscillation of the tube (about 40 centimeters) delivering about five watts at 50 centimeters and about one watt at 42 centimeters. These small amounts of power when used with sharply directive horn radiators have proved sufficient both for measurement of radiation characteristics with very simple detectors and for flight tests. Modulation of the radio-frequency output was accomplished by inserting in series with the direct plate voltage an audio-frequency voltage obtained from a vacuum-tube oscillator-amplifier unit. When overlapping radio beams were used for production of glide-path signals, the oscillators were modulated at 90 and 150 cycles per second respectively. Voltage-regulated power supplies in both plate and filament circuits of the oscillators were necessary for the production of stable signals. With constant voltages applied to the oscillators and with reasonable care in their adjustment, however, the frequency drift was small enough so that the oscillators would operate for several hours without retuning them or the receiver.

The first application of the "klystron" outside the Stanford Laboratories was made in this research through the courtesy of the Sperry Gyroscope Company, Incorporated, Stanford University, and the United States Army. Oscillators of this general type[7] are capable of producing several hundred watts of power at wave lengths in the neighborhood of 40 centimeters with an efficiency considerably greater than that of ordinary vacuum-tube circuits operating in the same wave-length range. Modulation of the klystron oscillator was accomplished either by variation of the voltage accelerating the electron beam, or by modulation of the radio-frequency output in the transmission line connecting the klystron to its load.

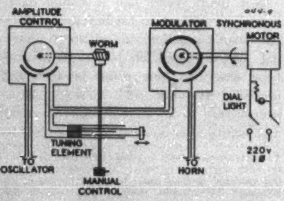

Figure 9. Schematic diagram of transmission-line modulator

Figure 10. Triode grid-leak detector with cover removed

For modulation in the transmission line, a mechanical modulator of the type shown in figure 9 was developed. The operation of this type of modulator is based on the fact that a variable capacitor inserted in series with the center conductor of a coaxial transmission line may be used to control the power transmitted through the line. A capacitor is rotated at such a speed that its reactance is varied at the desired modulation frequency, thus modulating the power delivered to the load. A second series capacitor, adjusted manually, serves as an amplitude control to determine the average amount of power transmitted through the modulator. An additional control is provided in the form of a short-circuited coaxial transmission line of adjustable length, connected across the transmission line between the amplitude control capacitor and the modulating capacitor. When correctly adjusted, the modulator will produce very nearly sinusoidally modulated signals with a modulation factor of about 0.95.

The Airplane Receivers

A preliminary calculation showed that a power of less than one watt delivered to an antenna with a power gain of 30 would produce a signal of one millivolt per meter at seven miles if free-space conditions prevailed. This is a fairly strong signal even for simple superheterodyne receivers. With a receiver of this sensitivity adapted for 600 megacycles, ranges of about five miles should be possible with at least one currently available triode (Western Electric 316-*A*). Since a power gain of 50 is provided in the actual antenna, distances of five to ten miles should therefore be expected. On the other hand, if a great deal more power is available at the transmitter, much simpler receivers should prove satisfactory.

The ultrahigh frequencies (approximately 700 megacycles) used necessitated the development of special radio receiving equipment for use in the airplane. The first receiver constructed was a triode grid-leak detector followed by an audio amplifier. A photograph of this unit with the cover removed is shown in figure 10. This simple receiver was satisfactory for use with a high-powered transmitter such as the klystron, but experience with it demonstrated that greater sensitivity and greater freedom from vibration effects would be very desirable. A novel superheterodyne receiver which fulfilled both of these requirements was therefore constructed.

In this superheterodyne receiver the 700-megacycle signal is fed directly into the converter which mixes the incoming signal with the third harmonic of the local oscillator and produces a 10-megacycle beat-frequency signal. This beat frequency is fed to the intermediate-frequency amplifier where it is amplified with no greater difficulty than any other 10-megacycle signal. The converter uses a diode and a combination of lumped and distributed circuit elements that are tuned to the frequencies of the 700-megacycle signal, the 230-megacycle local oscillator, and the 10-megacycle intermediate-frequency amplifier. An equivalent circuit diagram of the converter is shown in figure 11. The circuits *A*, *B*, and *D*, are all connected in series with the diode in such a manner that a voltage appearing in any one of them is impressed across the diode substantially independently of those appearing in the others. This independence is accomplished by making use of the difference in impedance of the

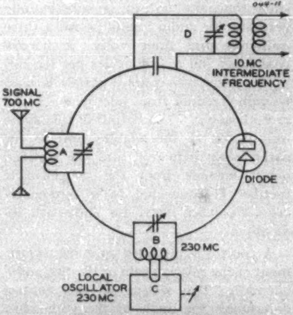

Figure 11. Equivalent circuit of converter of the superheterodyne receiver

three tuned circuits at widely separated frequencies. The local oscillator voltage is fed into the 230-megacycle circuit, *B*, and the diode generates in itself the third harmonic needed to mix with the 700-megacycle signal from circuit *A*. The special diode (*D*157653) used in this circuit was made available to us by the Western Electric Company.

The local oscillator *C* is of the type developed by A. P. G. Peterson[8] with the exception that the negative high-voltage lead is grounded to make possible the installation of the oscillator on the receiver chassis. The tube used is an RCA 955. The oscillator frequency is approximately 230 megacycles, adjustable over a small range. This frequency is low enough so that relatively stable oscillations may be obtained. Since the oscillator frequency is so far removed from that of the incoming signal, there is no danger of the oscillator synchronizing or locking-in with the received signal.

The 10-megacycle intermediate-frequency amplifier consists of two 1852 stages feeding a 6*SQ*7 second-detector audio-amplifier tube. A small amount of automatic volume control is incorporated in this amplifier, which has a gain of roughly 5,000 and a band width of approximately 300 kilocycles.

An elaborate audio-frequency amplifier follows the superheterodyne receiver proper and incorporates four stages of resistance-coupled amplification with automatic volume control, a separating filter for 90 and 150 cycles per second, separate one-stage amplifiers following the filter, and a copper-oxide rectifier system to feed a d-c indicating meter. The audio automatic volume control was provided mainly to allow the use of this amplifier with the grid-leak detector unit which has no automatic volume control of its own. The regulation is such that the output is substantially constant for audio inputs between three millivolts and three volts. A narrow pass band (50 to 400 cycles per second) in the resistance-coupled stages is used to gain freedom from microphonics and motorboating. The output of this audio unit is fed to the adapter unit of the cathode-ray indicator, and the rectified direct current from the copper-oxide rectifier is connected to a zero-center crossed-pointer meter for glide-path indication.

A control is provided to allow adjustment of the relative gain of the two audio channels. The setting of this control determines the angle of the glide path with respect to the ground. This control may be set so that the approach path angle is correct for a given type of airplane. This arrangement does not require a readjustment of the ground station to set the glide angle.

Figure 12. Complete superheterodyne receiver

The complete superheterodyne receiver was mounted on a plywood board supported by double shock-proof mountings—an arrangement which was fairly effective in suppressing vibration. A photograph of the equipment as it was installed in an airplane for flight tests is shown in figure 12.

The antenna was a coaxial type[9] connected to the receiver by a one-quarter-inch copper coaxial line. A short section of the line next to the receiver was made flexible to prevent transmission of mechanical vibration.

Flight Tests

Exploratory flight tests of a beam from a single horn were made at the Boston Municipal Airport mainly to determine workable range with a klystron power source and the simple receiver of figure 10. These tests also demonstrated that a substantially straight constant-intensity glide path could be realized by means of a single-horn radiator. Signals were received up to a distance of eight miles and simulated instrument landings were made repeatedly on this beam by the constant-intensity method over distances of about four miles.

Flight tests of the complete system were made in September 1939.* Two horns, energized by separate low-power triode oscillators, were used to provide the overlapping-beam pattern. Utilizing the superheterodyne receiver and the instrument already described, a straight-line landing path at an angle of about three degrees with the ground was flown consistently over a distance of somewhat more than five miles. These tests established the straightness of the microwave path over its entire length, and the feasibility of using the cathode-ray indication and three-light illusion as initially contemplated.

At this same time a klystron was again made available. With an estimated power of 50 watts supplied to one of the horns and using the superheterodyne receiver, flight tests demonstrated that extremely strong signals were received at a distance of 25 miles and an altitude of 2,500 feet. This performance leads us to believe that usable landing signals may be obtained at distances of the order of 50 to 75 miles.

Conclusions

In the course of the solution of the problem set forth at the beginning of this paper a landing system has been evolved embodying both a unique indicating instrument and landing path. The two elements, although used in combination in the system described, can also be applied independently. For example, the instrument may be used with constant intensity glide path and the straight-line glide path may be used with a conventional crossed-pointer instrument.

The landing path described in this paper marks a significant advance not simply because it is straight, and of an equisignal nature, but because it demonstrates a means by which a path essentially free from the effects of ground and surrounding objects may be realized. In this respect also the system describes an advance over conventional ones.[10]

The radio beam being thus substantially free from the effects of its surroundings makes the landing path reproducible and therefore makes the system truly portable.

The beams used for this landing path have other applications. For instance they may be utilized as vertical markers† where they are of value because of their extreme sharpness.

Not many years ago it would have been improvident to predict that within one year a practical 50-centimeter landing system based on the experimental type described here could be installed for pilot training, and it would have been heresy to say that within two years a 10-centimeter system could be made available for this purpose, yet now such is our confidence that on the basis of contemporary developments in the industry and elsewhere these predictions may now be made with reasonable assurance of fruition.

---

* The system as projected contemplated the use of centimeter waves for both pairs of beams. It was felt however that a standard localizer could also be utilized. This was done in these tests for which an Airtrack localizer was lent and operated by the Washington Institute of Technology.

† In this research horn radiators were used as markers both singly and in pairs. It is safe to say that the radiated pattern may be made as sharp as necessary by suitable design. The use of the modulated cross beams yields an approach signal, an instantaneous "over the marker" signal, and a departure signal.

In conclusion we wish to acknowledge the interest of the United States Army and the industry in this project. The Army made itself familiar with the work not long after its inception and has since, through co-operation, confirmed many of our observations. This interest can, we think, be taken not only as an index of the importance of centimeter-wave technique in air navigation but also as a recognition of the possibilities of research on critical problems through the co-operation of the government and the industry with technical institutions such as the Massachusetts Institute of Technology.

Compressed Powdered Molybdenum Permalloy for High-Quality Inductance Coils

V. E. LEGG
MEMBER AIEE

F. J. GIVEN
ASSOCIATE AIEE

Synopsis: Molybdenum-Permalloy is now produced in the form of compressed powdered cores for inductance coils. Its high permeability and low losses make possible improved quality or decreased size without sacrificing coil performance. Its low hysteresis loss reduces modulation enough to permit application where large air-core coils would otherwise be required.

THE introduction of loading coils in the telephone system at about the turn of the century brought special demands on magnetic and electrical properties of core materials, and set in motion investigations which have had wide influence on the theoretical and practical aspects of ferromagnetism. The first step in this development led to cores of iron wire, which sufficed for loading coils on circuits of moderate length.[1] With the development of telephone repeaters and the extension of circuits to transcontinental length some 25 years ago, there arose need not only for loading coils, but also for network coils, which would have high stability with time, temperature, and accidental magnetization. Magnetic stability was at first secured[2] by employing iron-wire cores provided with several air gaps. Later, commercial and technical considerations led to a core structure made from compressed insulated powdered material, first electrolytic iron[3] and later Permalloy powder.[4] This type of core is mechanically stable; it introduces in an evenly distributed fashion the requisite air gaps, while avoiding undesirable leakage fields; and it subdivides the magnetic material so as to reduce eddy-current losses. Although other means have been suggested,[5,6] no way has yet been devised which provides these features so well and at so low a cost as the compressed powdered type of core.

Loading-coil cores made from electrolytic-iron powder generally satisfied the stability requirements for long lines, but on account of their low magnetic permeability they were large and costly. The search for materials with higher permeability and lower hysteresis loss led to Permalloy[7] which, by 1925, had been produced in powdered form and fabricated into cores. This development provided coils for voice-frequency applications (loading coils and filter coils) which were cheaper and yet superior electrically to those made from electrolytic iron. These coils became available at a time when the telephone plant was undergoing a very large extension of loaded cables. As a result, large economies in cost and space were realized in the more than 6,000,000 coils involved in this plant expansion.

Iron powder, and later Permalloy powder, ground to a finer size and diluted to lower permeability than used in loading coils, also found application in coils for oscillators, filters, and networks of multiplex carrier telephone and telegraph systems employing frequencies up to 30 kilocycles[8] and in receivers for transoceanic radiotelephone communication employing frequencies up to approximately 60 kilocycles.[9] Permalloy powder improved the electrical characteristics—particularly modulation—of coils for use in high-frequency circuits, because of its low hysteresis losses.

Continued research for a powdered material having still better intrinsic properties has recently made available new compressed powder cores which permit further important gains in coils for voice-frequency circuits and in coils for high-frequency carrier system applications. The latter take on considerable significance at this time because they play an important part in making practical for commercial use the new broad-band carrier telephone systems intended for use on existing open wire and cable lines and on new types of cable. Again, therefore, the advent of a new core material is well-timed to be of assistance in further growth of the telephone system.

Paper 40-20, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted June 21, 1939; made available for preprinting December 12, 1939; released for final publication February 16, 1940.

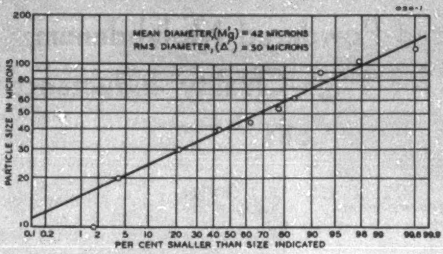

Figure 1. Distribution of particle size of 120-mesh powder, by weight

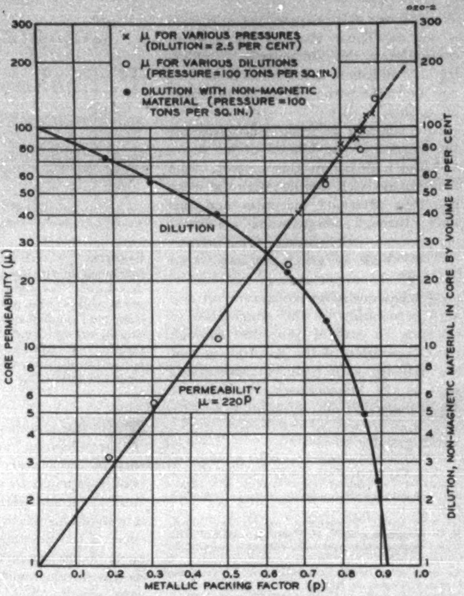

Figure 2. Relation between metallic packing factor, permeability, and percentage dilution

The development of this core material was based on the discovery[10] that the addition of a small percentage of molybdenum to Permalloy increases its permeability and electrical resistivity, and decreases its eddy current and hysteresis losses. Decreased losses are necessary for improvements and economies for both voice-and carrier-frequency operation. The increased permeability of this alloy is essential for the improvement of voice-frequency coils. It is readily reduced to the proper values for high-frequency coils by diluting the powdered magnetic material with insulating material before compressing into core form. In this development many problems of alloy embrittlement, pulverization, insulation, and heat treatment had to be solved both on a laboratory and factory scale. The alloy composition finally selected as giving the best combination of desirable properties, contains approximately 2 per cent molybdenum, 81 per cent nickel, and 17 per cent iron, and is designated as 2–81 molybdenum-Permalloy. This new alloy is manufactured commercially by the Western Electric Company for use in loading coils and filter coils.

Physical and Magnetic Characteristics

The raw materials and necessary embrittling agents[11] are melted together and cast into ingots which are rolled to develop the desired grain structure. The density of this alloy is 8.65 grams per cubic centimeter. The brittle material is pulverized to the desired fineness and finally annealed to soften the alloy particles before insulation and pressing into core form.

The distribution by weight of the particle sizes of a sample of 120-mesh powder is given in figure 1, showing a root-mean-square size of 50 microns.[12] Since the effective resistance of a coil due to eddy-current losses in its core is proportional to the mean-square particle diameter[13] it can be decreased when desired by the use of more finely pulverized material.

The problem of insulating 2–81 molybdenum-Permalloy powder is to coat the particles with a minimum thickness of a material which will not break away during the pressing operation, which will not fuse and flux the magnetic particles together during the core heat treatment, which will prevent the flow of eddy currents between metallic particles, and which will be chemically inert throughout the lifetime of the magnetic core. The difficulty of the problem will be appreciated from the fact that the separation between adjacent particles of a core of 125 permeability is approximately equal to the wave length of visible light (0.5 micron). This thickness of insulating film may be shown to be approximately $rt/300p$, where r is the percentage of insulating material by volume, p is the packing factor of the magnetic material, and t is the rms particle diameter (assuming spherical particles).

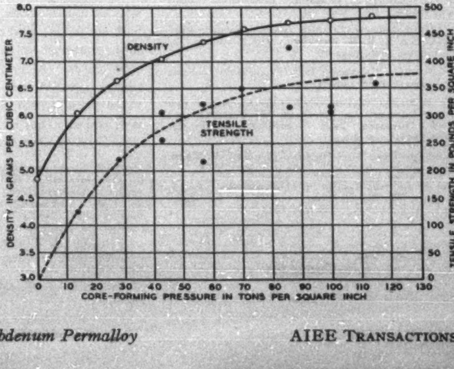

Figure 3. Effect of core forming pressure on density and tensile strength

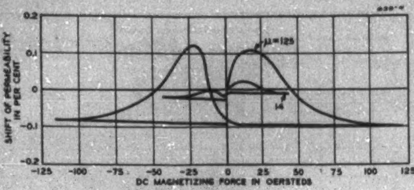

Figure 4. Residual effect of d-c magnetization on initial permeability—measured three minutes after release of direct current

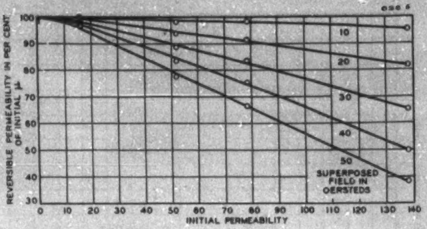

Figure 5. Effect of superposed magnetization on permeability

A new type of ceramic insulation has been introduced with these cores which fulfills the above requirements and which is more inert than the previous type. This new insulating material is free from water-soluble residue. It thus eliminates the final washing treatment which was required with the earlier type.

For applications where a low permeability is desired, nonmagnetic powder is added to further dilute the magnetic material. The permeability of the finished core depends largely on the quantity, particle size, and thoroughness of admixture of nonmagnetic powder. Various attempts to derive theoretical relations between core permeability and dilution have been made,[14,15] but they generally fail in some detail. An empirical representation of this relationship is found to be

$$\mu = \mu_i^p$$

or

$$\log \mu = p \log \mu_i,$$

where μ_i is the intrinsic permeability of the magnetic material, and p is the packing factor, or fraction of the core volume occupied by magnetic material. This equation is found to be valid for a wide range of dilution, effected either by adding insulating material or by reducing the load during core compression. However, the intrinsic permeability must be determined experimentally for each type of particle, size distribution, method of admixture of nonmagnetic powder, and annealing process. Figure 2 shows curves of permeability and percentage diluting material versus metallic packing factor. A permeability of 125 has been selected for most loading-coil cores, while permeabilities of 14 and 26 have been chosen for two important types of high-frequency filter coils.

A pressure of 100 tons per square inch is employed in forming molybdenum-Permalloy cores, to attain proper density and mechanical strength. The effect of pressure on core density and strength is shown in figure 3 for cores having 2.5 per cent dilution. The tensile strength of diluted cores is decreased somewhat; for example, cores with 25 per cent nonmagnetic materials have a tensile strength of about 250 pounds per square inch.

In annealing the compressed cores to remove stresses incident to pressing, it has been found that the insulating material remains intact at a considerably higher temperature if oxygen is excluded. An improved annealing treatment has therefore been introduced by which the cores are heated in an atmosphere of hydrogen, with the attainment of high core permeability and low hysteresis loss. The ability of the insulating material to withstand such a heat treatment testifies to its extreme stability and recommends it in preference to organic materials.

An essential core requirement of precision inductance coils is that the permeability remain unaltered during the life of the coil. The greatest difficulty with cores having no air gaps is the large and more or less permanent shift of permeability due to accidental strong magnetization. Such variations have recently been overcome to a degree in continuous

P—With Permalloy core
MP—With molybdenum-Permalloy core

cores made of hard rolled nickel-iron alloy sheet,[8] but they have been found to be rather large immediately after strong magnetization, decreasing slowly to tolerable limits only after two or three days. With compressed powdered molybdenum-Permalloy cores, permeability shift due to strong magnetization is remarkably small, even within a fraction of a minute after the magnetization is released, and any further drift of permeability with time is negligible. In typical cores of the new material, the shift in permeability after strong magnetization is less than 0.2 per cent for cores of permeability 125, and less than 0.05 per cent for cores of permeability 14. Figure 4 shows the residual effect of the application and removal of various magnetizing forces on cores of both these permeabilities.

When a direct current is superposed on an alternating current in the windings of a coil, the inductance is altered because the magnetic field set up by the direct current modifies the core permeability. Figure 5 shows the effect of superposed d-c fields on the permeability of 2–81 molybdenum-Permalloy powder cores of various permeabilities.

A further important core property is the constancy of permeability with respect to flux density *B*. This is of particular importance in precision filters, to insure that changes in transmission level do not produce serious alterations in the frequency discrimination characteristics. Figure 6 shows the superiority of the new material over the earlier Permalloy.

A new requirement for cores has been introduced by quartz-crystal filters used in wide-band carrier systems. In order to secure the necessary precision in this type of filter, measures have to be taken to prevent departures from the initial frequency adjustment due to changes in core permeability ordinarily occurring with room-temperature changes. Extremely small temperature coefficients of permeability have now been achieved by adding to the new 2–81 molybdenum-Permalloy powder a very small percentage of special Permalloy powder having a molybdenum content of about 12 per cent. Such an alloy has a nonmagnetic or Curie point close to room temperature, and for a small temperature range just below its Curie point, it has a negative temperature coefficient several hundred times as large as the positive coefficient of 2–81 molybdenum-Permalloy. By choosing suitable compositions and percentages of such compensating alloys, the net temperature coefficient of permeability of a core can be adjusted to any reasonable value, positive or negative, over a desired temperature range. Figure 7 shows a permeability versus temperature curve for a core stabilized to give a small negative coefficient, compared to a similar curve for a core not stabilized.

Core Losses

The desirability of core materials increases in general as their loss characteristics decrease. Low total eddy-current and hysteresis losses give low contributions to attenuation. Hysteresis loss is frequently of especial importance because it appears fundamentally as a resistance which varies with coil current, and because it incidentally generates harmonic

Table I. Loss Coefficients of Powdered Core Materials

Material	μ	Hysteresis $a \times 10^6$	Hysteresis $\mu a \times 10^3$	Residual $c \times 10^6$	Residual $\mu c \times 10^3$	Eddy Current $e \times 10^9$	Eddy Current $\mu e \times 10^6$
Grade *B* iron	35	49	1.7	109	3.8	88	3.1
Grade *C* iron	26	81	2.1	139	3.6	31	0.8
81 Permalloy	75	5.5	0.41	37	2.8	51	3.8
	26	11.5	0.30	108	2.8	27	0.7
2–81 molybdenum-Permalloy	125	1.6	0.20	30	3.8	19	2.4
	26	6.9	0.18	96	2.5	7.7	0.2
	14	11.4	0.16	143	2.0	7.1	0.1

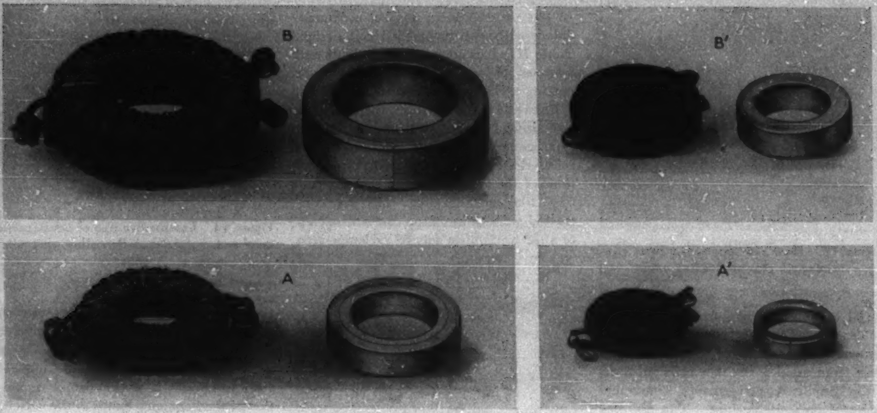

Figure 10. Comparative sizes of the new molybdenum Permalloy (A,A′) and the superseded Permalloy (B,B′) cores and coils

Right—Exchange-area loading coils

voltages. A low value of hysteresis loss thus simplifies circuit problems arising from resistances which vary with energy level, and it avoids troublesome modulation conditions.

The total resistance per unit inductance arising from eddy-current and hysteresis losses may be expressed as[16]

$$R_m/L=\mu(aB_m+c)f+\mu ef^2$$

where the symbols are as given in the appendix.

Table I gives the loss coefficients for various core materials, and for 2-81 molybdenum-Permalloy insulated to several permeabilities. The low loss coefficients of the new material as compared with the best previous materials are of importance from two standpoints. First, core permeabilities as much as 50 per cent greater can be now utilized in coils without increasing the total core-loss resistance. Second, by utilizing the same permeabilities, core-loss resistances about 60 per cent smaller can be obtained.

In many coil-design problems, harmonic generation or modulation assume controlling importance. The modulation factor *m* which denotes the ratio of the generated third harmonic to the applied voltage may be expressed as follows:[17]

$$m=E_3/E_1=3\mu aB_m/10\pi$$

The low values of *a* obtained with the new material yield values of *m* that are about 6 decibels and 20 decibels lower than possible with powdered Permalloy and electrolytic-iron cores, respectively.

The wide range of core permeability available with this new material permits a ready choice of the proper values of permeability and core size to suit any particular needs. In the usual design problem the following main requirements must be considered, in addition to providing the desired inductance.

1. D-c resistance, R_c
2. Coil quality factor, $Q = \omega L/(R_c+R_m)$
3. Modulation factor, *m*
4. Coil size (which depends directly on core size)

Table II. Comparative Size and Weight Data of Typical New and Superseded Coils

Type of Coil	Type of Compressed Powdered Core	Inductance (Henrys)	Coil Volume (Cubic Inches)	Coil Weight (Pounds)
Small exchange area	Permalloy	0.088	2.5	0.4
	Molybdenum-Permalloy	0.088	1.5	0.2
Program circuit	Permalloy	0.022	11.8	1.6
	Molybdenum-Permalloy	0.022	4.4	0.6
Toll-side circuit	Permalloy	0.088	13.5	1.7
	Molybdenum-Permalloy	0.088	5.1	0.7

These requirements cannot be satisfied independently however, as fixing any two of them automatically fixes the values of the others. In each case, a particular value of core permeability is required for the proper fulfillment of the conditions. The appendix lists the formulas essential to the determination of these factors. Although these formulas imply an entire freedom of choice of core permeability and size, it becomes necessary for practical purposes to standardize on a limited number of values of permeability and a limited number of sizes of core. It is possible by the proper choice from these types to approach rather closely to an ideal solution for each problem.

Improved Designs of Loading Coils

A study of alternate ways of utilizing the advantages offered by the new ma-

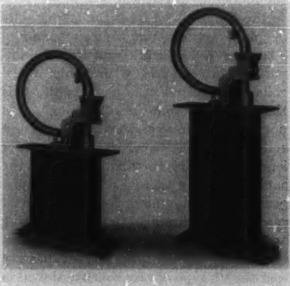

Figure 11. New and superseded cases containing 200 exchange-area coils

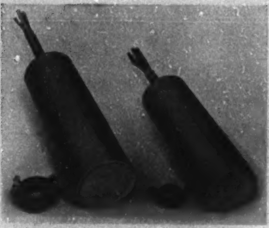

Figure 12. New and superseded cases containing six program-loading coils

terial in coils for voice-frequency loaded cables showed that the greatest immediate benefit to the telephone plant would accrue from making the new coils substantially duplicate performance characteristics of previous designs. The new designs chosen are in fact better in most respects and have been made approximately 50 per cent smaller in volume by using a molybdenum-Permalloy core with a nominal permeability of 125. Table II summarizes data comparing the electrical characteristics, sizes, and weights of coils commonly used on exchange and toll cables. Figure 8 shows the improved resistance-frequency characteristics for typical coils. Figure 9 shows the improved telegraph flutter[18] characteristics of a commonly used toll-type coil.

Figure 10 pictures the reduction in size of cores and coils which are commonly used in toll and exchange area circuits. In the preparation for commercial manufacture of the smallest of the new coils, a difficult problem in the development of winding machinery was involved because of the small dimensions of the hole in the finished coil. This problem has been successfully solved by the Western Electric Company.

Aside from manufacturing economies, the reduction in coil size is of importance to the Bell System from the standpoints of plant construction and installation. The size reduction is particularly important in instances where only a few coils are required at a given point, as is the case in program-circuit loading. It is now practicable to enclose as many as six coils, even of the larger size employed for loading program circuits, directly in the cable splice at a loading point. This dispenses with the need for conventional cases, and reduces both manufacturing and installation costs. In the field of small complements using the inexpensive lead-sheath type of case construction, it is now possible to furnish as many as 100 of the small exchange area coils whereas 15 was the maximum number accommodated with the superseded coil design. Table III gives comparative weights and volumes of typical cases provided for potting exchange area and toll-type coils.

Figures 11 and 12 show the comparative sizes of typical steel and lead-sleeve type cases for the new and superseded coils. In figure 13, the midget proportions of the latest design of case for potting 100 exchange-area coils are contrasted with those of the case utilized up to 1922 containing only 98 exchange-area coils. The reduction in size of cases for this type of coil is of particular importance in larger cities where underground vault space is at a premium.

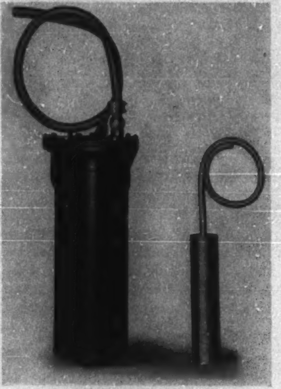

Figure 13. Comparative size of equivalent 1939 and 1922 cases

Improved Inductance Coils for Filters

The trend of development of toll transmission circuits is now very definitely toward multiple-channel carrier systems utilizing a much wider frequency band than has heretofore been employed on wire circuits.[19,20] These systems involve extensive use of selective or equalizing networks at terminals and at repeater stations in order to obtain proper separation of the frequency bands of the various channels or to insure suitable transmission properties of the individual channels. While these networks involve coils, capacitors, and crystals, it is frequently the case that their size, cost, and performance are determined chiefly by the quality factor Q of the inductance coils. This follows from the fact that Q values of coils are usually considerably lower than those obtainable readily in capacitors and crystals. Accordingly, it is very desirable to have as high a value of Q as possible economically. In addition, such coils must have low hysteresis resistance to limit modulation, and a low temperature coefficient of inductance to secure stability of attenuation or impedance characteristics of the filters and networks.

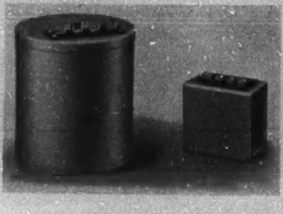

Figure 14. Comparative size of nonmagnetic core and molybdenum-Permalloy core filter coils

Due to the improvements in these respects, molybdenum-Permalloy core coils can be used quite extensively in new types of carrier telephone systems. In such systems for existing lines and cables, as well as for projected new types of cables, those filters are of key importance which separate individual message channels in the frequency range from 3 to 108 kilocycles. By using coils of powdered molybdenum-Permalloy insulated to permeabilities of 14 or 26, valuable economies in space and cost of filters are

Table III. Comparative Data on Representative Cases for New and Superseded Loading Coils

Figure 15. Comparative Q-frequency characteristics on typical filter coils using new and superseded materials

realized.[21,22] Figure 14 shows a typical coil employing a 14 permeability core designed for use in one of these channel filters having its transmitted band in the vicinity of 108 kilocycles, together with a shielded solenoidal air-core coil which might be employed for the same purpose. The molybdenum-Permalloy coil has a Q at 100 kilocycles about twice that of the air-core coil, yet it occupies approximately one-tenth as much space. The third-order modulation products are approximately 80 decibels below the level of the normal channel currents. This is considered to be tolerable from the standpoint of interchannel cross talk on circuits used for one-way transmission. An inductance-temperature coefficient of about -20×10^{-6} per degree Fahrenheit has been chosen to compensate for the positive capacity-temperature coefficient of associated capacitors.

In figure 15 data are presented illustrating the Q-frequency characteristics that can be obtained on typical coil designs using the new material in the frequency range from 300 cycles to 200 kilocycles. The characteristics shown apply to coils wound on three sizes of cores that are suitable for use in this range. For comparison, similar characteristics are also included for coils using cores of equal size but made of Permalloy and electrolytic-iron powder. These data include all effects on Q resulting from winding capacities and losses, which have been made tolerably small by suitable choice of insulating materials, stranding of conductor, and configuration of winding.

Conclusion

Compressed powdered cores of 2–81 molybdenum-Permalloy have properties which are superior to those of earlier powdered cores in respect to permeability range, hysteresis loss, and eddy-current loss. Because of the lower losses and greater permeability range, inductance coils are now possible which have greatly increased Q values for a given volume. Because of the low hysteresis losses and attendant lowering of modulation effects to tolerable levels, magnetic-core inductance coils can now be employed where nonmagnetic core coils have previously been necessary, with a very great increase in Q values for a given volume. Temperature coefficients can now be obtained which are equal to the temperature coefficients of other high-grade electrical elements such as mica capacitors and quartz crystals. Moreover, the ability to make the temperature coefficient of coils negative or positive at will permits the attainment of remarkable stability in resonant combinations of coils and capacitors Two important applications have been made in the field of communication apparatus. For voice-frequency circuits, new loading coils of improved quality and reduced size have been standardized. For broad-band carrier systems, the compactness of channel separating filters is largely due to the volume economies introduced by molybdenum-Permalloy coils.

Appendix

The following formulas illustrate the essential steps in selecting the size and permeability of an annular core best suited for a coil having a desired set of characteristics. For sake of simplicity, they assume throughout a coil of arbitrarily chosen proportions, in which all dimensions bear fixed ratios to the mean core diameter, approximating those that are practicable from a manufacturing standpoint. The core is assumed to be rectangular in section. It is assumed that wire of any diameter can be used and that the winding efficiency is independent of the wire diameter. Any inductance due to air space outside of the core is neglected. Because of these simplifications, the expressions are of somewhat restricted applicability. However, they yield solutions for optimum permeability and corresponding values of Q and core size which are sufficiently accurate for most practical purposes.

The inductance in henrys due to a core of permeability μ, and mean diameter d centimeters, wound with N turns of wire is

$$L=\frac{3}{8}N^2\mu d\times10^{-8} \qquad (1)$$

If the coil is wound with wire of resistivity ρ_c ohm-centimeter, with winding efficiency s (that is, the ratio of copper area to total available winding area), the d-c resistance in ohms will be

$$R_c=\frac{19\rho_c L\times 10^9}{s\mu d^2} \tag{2}$$

The maximum flux density due to sine-wave measuring current of effective value I amperes is

$$B_m=\frac{8I}{5}\sqrt{\frac{\mu L\times 10^9}{3d^3}} \tag{3}$$

In terms of the hysteresis loss coefficient $k_2=\mu a$, the modulation factor thus becomes[17]

$$m=\frac{E_3}{E_1}=\frac{3k_2B_m}{10\pi}=\frac{4k_2I}{25\pi}\sqrt{\frac{3\mu L\times 10^9}{d^3}} \tag{4}$$

or

$$d^3=3\mu L\times 10^9\left\{\frac{4k_2I}{25\pi m}\right\}^2 \tag{5}$$

When the core permeability μ is reduced by dilution of a given material, the hysteresis and residual loss coefficients a and c vary so as to make the products $\mu c=k_1$ and $\mu a=k_2$ approximately constant, as may be seen by reference to table I. The core-loss resistance in ohms at frequency f cycles per second may therefore be expressed with reasonable accuracy as

$$\begin{aligned}R_m&=Lf(k_1+k_2B_m+\mu ef) \qquad (6)\\&=Lf\left(k_1+\frac{10m\pi}{3}+\mu ef\right)\end{aligned}$$

where the eddy-current coefficient e depends upon the particle diameter t, and the alloy resistivity ρ, being proportional[18] to t^2/ρ.

The coil quality factor is thus

$$\begin{aligned}Q&=\frac{2\pi fL}{R_c+R_m}\\&=\frac{2\pi f}{\dfrac{19\rho_c\times 10^9}{s\mu d^2}+f\left(k_1+\dfrac{10m\pi}{3}+\mu ef\right)} \qquad (7)\end{aligned}$$

Case I. If the value of m is fixed and d and R_c can be freely chosen, it is desirable to know the value of μ which will yield the highest possible value of Q. By substituting in (7) the value of d^2 obtained from (5) and setting the derivative with respect to μ equal to zero, the following is obtained for the optimum permeability:

$$(\mu')^8=\frac{52.5\times 10^{18}\rho_c^3m^4}{e^3s^3f^3k_2^4I^4L^2} \tag{8}$$

The corresponding values of d and R_c can be obtained from equations 5 and 2. The corresponding value of Q, which is the greatest obtainable under these conditions is

$$Q'_{\max}=\frac{\pi}{\dfrac{5m\pi}{3}+\dfrac{k_1}{2}+\dfrac{4}{5}\mu' ef} \tag{9}$$

If a smaller value of Q than that obtained from (9) is acceptable, equations 7 and 5 can be solved simultaneously for d and μ. A smaller value of μ than that obtained from (8) and a correspondingly smaller value of d will result.

Case II. If modulation is unimportant and the hysteresis-loss resistance is negligible in comparison with other component losses, then d and μ can be selected without regard to modulation. Equation 7 can be differentiated directly and solved for the permeability required to yield the maximum value of Q. This optimum permeability is

$$(\mu'')^2=\frac{19\rho_c\times 10^9}{sed^2f^2} \tag{10}$$

The corresponding value of Q is

$$Q_{\max}''=\frac{2\pi}{k_1+2\mu'' ef} \tag{11}$$

The values of $Q_{\max}''$ and μ'' depend on the value of d chosen. For a desired value of Q, (11) can be solved for μ'', and (10) for the corresponding diameter.

In any case, the ideal wire size has a cross-sectional area of conductor equal to

$$0.15sd^2\sqrt{\frac{\mu d\times 10^{-9}}{L}}\text{ square centimeters}$$

It is usually desirable to subdivide the wire into insulated strands to minimize eddy-current losses in the coil winding.

High-Speed Voice-Frequency Carrier Telegraph System

F. B. BRAMHALL
MEMBER AIEE

NARROW-BAND voice-frequency carrier telegraph systems for the operation of a single teleprinter over each carrier channel have been developed to a high degree of perfection both in this country and abroad. These have been admirably described in technical literature. The theory and basic principles of carrier systems have also been well covered. This paper therefore will confine itself to a working description of a wide-band system developed to meet the requirements of a telegraph plant in which all trunk traffic between large centers is handled by the multiplex telegraph method of operation in which three or four automatic printers are operated over each carrier channel. For those not familiar with telegraph terminology and practices a brief exposition of the differences between single-printer operation and multiplex operation is perhaps in order. The single-printer method of operation secures synchronism between transmitting and receiving machines by means of what is known as the start-stop principle. A start pulse is transmitted by the sending machine preceding each group of five letters-code pulses and a rest pulse follows each group of code pulses. For 65 words per minute maximum printing speed the single-printer method results in a line frequency of 22.75 cycles per second. In the multiplex method of operation synchronism between transmitter and receiver is maintained without recourse to start and rest pulses, resulting in a more favorable ratio between printer words per minute and line signaling frequency. At a printer speed of 66 words per minute, the line frequency by the multiplex method is $16^1/_2$ cycles per second for each printer or 66 cycles per second on the four-printer circuit commonly used.

It is beyond the scope of this paper to compare the relative economies of the two methods of operation but it becomes at once apparent that the multiplex method makes for greater efficiency in the use of the frequency spectrum. There is first the improvement which results from the absence of the start and rest pulses amounting to over 40 per cent and second, the increase resulting from the use of wider carrier bands and the attendant reduction in the waste of spectrum required for channel separation in the tuners. The multiplex-carrier system here described operates normally at 66 words per minute on each of four printers, or 264 words per minute for each carrier channel. To each carrier channel, 300 cycles of spectrum is assigned. Single-printer systems require 150 to 170 cycles of spectrum for 65-word-per-minute signaling. The ratio of spectrum efficiencies secured is therefore at least two to one in favor of multiplex working. Practically, an added advantage results from the difficulty of operating start-stop printing machines at maximum speed, whereas the tape-storage feature of multiplex operation makes full theoretical speed easily attainable.

With somewhat over 700 multiplex circuits, on the conventional polar duplex ground-to-ground plan connecting the larger cities of the country, it was mandatory that the multiplex carrier system meet the well-established conditions of operation. Provision must of course be made for extending the circuits assigned to carrier channels in either or both directions beyond the terminal points of a given carrier system. The derived carrier channels must therefore conveniently and flexibly interconnect with the existing polar-duplex terminal and repeater equipment. Repeater spacing for carrier operation should preferably, though not necessarily, be the same as for grounded-duplex operation. Repeater-section distances for physical operation average about 250 miles, somewhat in excess of what in the past was considered reasonable repeater distances for voice-frequency circuits. Power plants available at physical telegraph repeater offices are not of the type commonly employed for voice-frequency operation, being in practically all cases only motor generator sets, not particularly closely regulated, nor free from the noises of load reaction and commutator ripple. In practically no case do these plants include stabilizing storage batteries.

General Design Features

Presuming at the outset of the development some years ago, a nominal operating speed of 60 cycles per second, but making allowance for the definite trend toward higher speeds, a channel band width of 180 cycles was established. This choice has long since been shown to be justified. Speeds have increased and standards of transmission efficiency have risen. A tuner design which has proven very practical for economy and space considerations permitted a channel spacing of 300 cycles. The term tuner employed in this paper indicates a network which passes a desired range of frequencies while rejecting those above and below. The system ultimately standardized employs frequencies of 450, 750, 1,050 cycles and so on with entirely practical extension up to 22 channels with the last at 6,750 cycles. In no case, however, have more than ten channels been required on any circuit although the upper channels have been tested and on one circuit the 16th channel, 4,950 cycles, has been in commercial service for a number of years. Generating equipment has been installed for all 22 channels for use as traffic increases may demand. All trunk-route circuits are operated on the four-wire

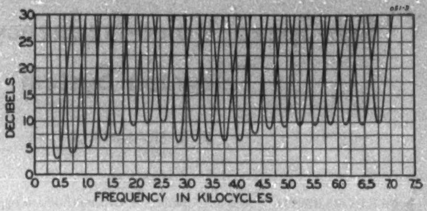

Figure 3. Transmission characteristics of receiving tuners

basis, one pair for transmission in each direction.

Wherever carrier routes have been established, open-wire transposition has been done with a view to utilizing frequencies at least as high as 7,000 cycles. Cable loading, while designed for this frequency has, on some routes, not been completely installed. On those routes where it appears that the need to use more than half this spectrum is not immediate, economies have been effected by, initially, installing only partial loading.

Impedance of all circuit elements has been established at 600 ohms, this being a value widely used in this country and sufficiently close to the nominal impedance of open-wire lines of standard telegraph construction.

Terminal Apparatus

The transmitting equipment comprises, in addition to a source of carrier frequency, the control or transmitting relay, and a transmitting tuner. Figure 1 shows a schematic diagram of the transmitting and receiving apparatus.

Transmission is accomplished by opening the carrier source as opposed to short-circuiting the source as is done in many other systems. This practice requires that the input side of the transmitting tuner be terminated in a matching impedance to prevent the appearance of objectionable transients which otherwise arise.

The tuners are multipled to a transmitting bus, the design being such that the impedance outside the pass range is high in comparison to 600 ohms. Ordinarily, level adjustments are made in the generator distributing equipment such that the power at the bus multiple point is minus ten decibels, or 0.1 milliwatt per channel. The aggregate signal of all channels of the system is led to a terminal repeater which, in every essential respect, is electrically and functionally identical to the intermediate repeaters, the description of which is left for a succeeding section.

The transmission characteristics of the transmitting and receiving tuners for the complete 22-channel system are shown by figures 2 and 3. The band width of the receiving tuners is 180 cycles and the discrimination against the side bands of the adjacent channels when modulated at 75 cycles is not less than 25 decibels. This amount of discrimination results in a telegraph transmission loss resulting from direct interchannel interference not in excess of five per cent when both the channel under test and the interfering channels are operated at 75 cycles, the nominal maximum speed of the system.

The transmitting tuners are somewhat wider in order not to restrict appreciably the useful band as determined by the receiving tuners. With an exception for the first two channels these tuners suppress the second-order side bands by at least 12.5 decibels. The above statement on direct interchannel interference presumes this degree of side-band suppression.

The incoming signals are delivered to the receiving bus at a level of plus ten decibels by a conventional repeater. Receiving tuners, with impedance characteristics similar to those at the sending end, deliver each channel band to an amplifier-detector by way of a simple potentiometer level control.

With the signal level at the output of the tuner in the neighborhood of 0.0 decibels, and the amplifier-detector capable of operating on a level of −8.0 decibels, ample margin for adjustment is afforded. The detector tube is preceded by a single stage of amplification, transformer coupled. The detector delivers a rectified signal of 60 milliamperes to the receiving relay, a polar relay operating with an electromagnetic bias. Incidentally, since the initial development work was done a number of years ago a great number of signal-shaping circuits, current-limiting rectifiers, and polar rectifiers have been investigated. The broad conclusion from this work has been that the effect of interference cannot be mitigated by such devices and that the only good they can be hoped to accomplish is in improving the speed and positiveness of the relay action. The relays now commonly used in high-speed telegraph service do not require or justify any signal-shaping device.

The local circuits operating and operated by the sending and receiving relays are designed to permit extension of the channel on either a single-wire polar-duplex basis or a two-wire sending and receiving leg basis, the former for extension of the channel to a distant point by the conventional method of working and the latter for connection to terminal equipment. Multiplex sets in the carrier terminal office are split for two-wire sending and receiving operation by means of a switch. Polar operation is employed on these two legs to avoid any unnecessary transmission loss. Morse monitoring equipment is provided with every channel, experience having shown that a common monitoring set sometimes entails delays in testing and circuit line-up work. Selectors are provided on a plug-in basis in order that they may be had where required, depending upon the circuit-channel assignment. Artificial lines, too, are provided on this basis. The local and monitoring circuits of the channel terminals may be altered to meet the mode of operation of five distinct classes of service by means of a multipoint switch. These include, besides local and extended multiplex, full or half-duplex teleprinter working either to separate operating positions or to concentrator units.

Mechanical design of channel terminal and repeater equipment is perhaps somewhat novel, being such as to permit full use of both sides of the mounting rack for live or adjustable units where required. Very little equipment is mounted on the rear of the panels and in no case does such apparatus project beyond the rear face

of the panel more than half of the depth of the rack channels. All wiring and interpanel connecting terminal blocks are accessible from the front. Figure 4 shows the layout of the channel terminal sets. Two are mounted per bay and four per mounting rack, the opposite face being an identical layout. Interpanel wiring is concealed in the metal duct with hinged doors to the left of the bay.

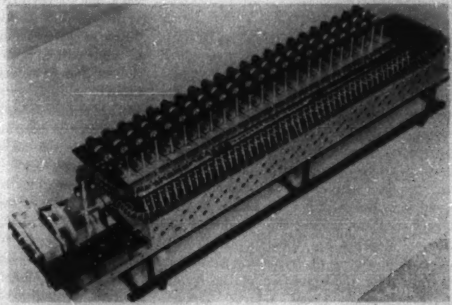
The sending and receiving busses, which multiple a group of channel terminal sets, appear on jacks on a carrier switchboard which controls the common sending and receiving amplifiers. These bus patch points are treated no differently however from a pair of line circuits, one east and one west, at an intermediate repeater point. The terminal repeater need therefore not be described in detail and those slight differences which do appear, having only to do with monitoring and system patching methods, will be pointed out in the section on repeaters. Before proceeding to the description of line and repeater equipment, however, the carrier-frequency generating and distributing equipment will be shown briefly.

Carrier-Frequency Supply

The carrier frequencies are derived from an inductor alternator. Those installed with the earlier systems were of a type designed to deliver, without amplification, sufficient power to supply ten carrier systems. These machines were driven from a primary source of d-c power with eight generating wheels on a common shaft and with the speed controlled by a centrifugal governor. A number of these are still in operation, supplying eight frequencies of ten channel systems, the last two frequencies being furnished by separate single-frequency auxiliary machines.

More recently installed systems employ an adaptation of the generator used in an electric organ. This machine, with minor modifications, fills the need admirably. New machines are equipped to deliver the carriers, spaced 300 cycles apart, for 22 channels. The generating wheels, while not on a common shaft nor rigidly locked in phase position, do not deviate

Figure 5. 22-channel carrier generator



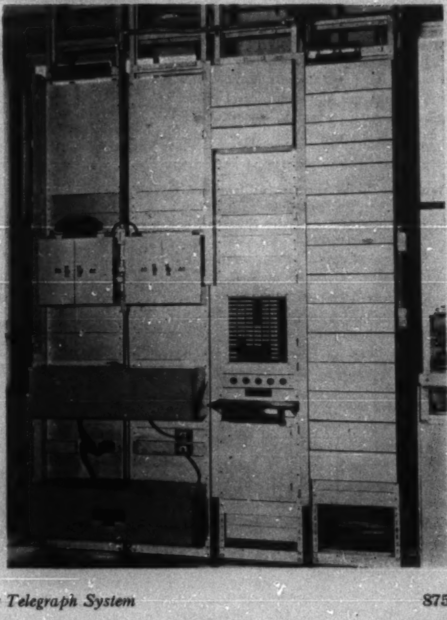


Figure 6. Carrier-supply bays

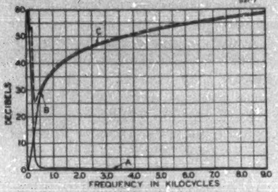

Figure 7. Transmission characteristics of composite

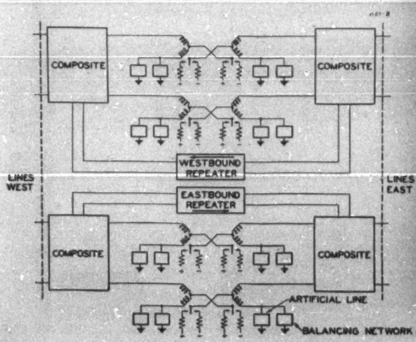
A—Line to carrier
B—Physical to line
C—Physical to carrier

appreciably from the nominal speed and experience has indicated that little is to be gained from exact phasing. This machine, as altered for carrier generation, is shown by figure 5. The 60-cycle synchronous driving motor has a total power consumption of 11 watts, small enough to be conveniently derived from an amplifier driven by a standard-frequency power source. In many of the larger centers where the terminals of carrier systems are located, the commercial power is of frequency stability adequate for the operation of the 6,750 cycle channel. Local reserve power plants, however, are not of adequate stability, so it is required to install standard-frequency power sources from which the motor may be driven in emergency.

The carrier pickup winding is wound directly on a permanent magnet which has its end suitably shaped and properly adjusted with respect to the rotor teeth. Two of these assemblies are located on diametrically opposite sides of the wheel, with the two pickup windings in multiple. Each carrier frequency, generated at a level of −30 decibels (one microwatt), is amplified by a two-stage amplifier to +30 decibels level.

Figure 8. Block diagram of four-wire repeater



A typical installation of generators, working and spare, together with amplifiers and distributing apparatus is shown by figure 6. The 22 frequencies are led to a distributing panel where multiples are made for all the carrier systems in an office. Associated with each carrier system but mounted on the generator bays is a pad panel which contains adjustable potentiometers of high attenuation, one for each frequency. These prevent interaction between like channels of different systems due to the load variation of modulation. An over-all level regulation of plus or minus 0.2 decibel is maintained by the generating, amplifying, and distributing equipment. The whole of the carrier-generation plant is designed to be subject to an absolute minimum of interruptions and every precaution is taken to be able to locate failures and restore service without delay.

In New York a plant of this type supplies carrier power for four systems with ten channels in operation on each. This plant has a capacity, as installed, of ten systems.

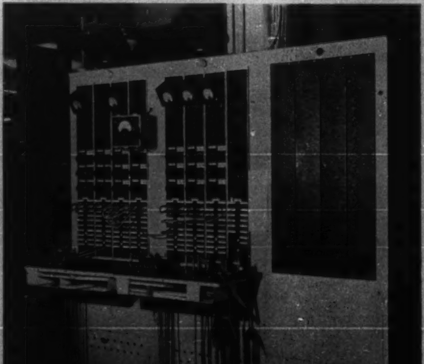
Compositing Equipment

All carrier wires are composited and the normal grounded-duplex operation on them is maintained without loss of flexibility in circuit assignment and with little loss of efficiency. The transmission characteristics of the composite are shown by figure 7. The presence of a low-pass filter section, required to suppress the voice-range components of the physical-circuit transmission, necessitates a compensating network in the artificial line of the physical repeater or terminal set. The connection of this network is so arranged in the switchboard circuit of the wire that it is associated always with the wire rather than the set, permitting complete freedom of set assignment and regulation. For the most part carrier repeaters are located at points which are also physical-circuit repeaters for economy of office facilities and attendance personnel. Near large centers of population, however, cable sections require the use of carrier repeaters intermediate to the physical repeaters. At such repeaters two composites are employed but are so connected as to insert no unnecessary attenuation in the physical telegraph circuit. The physical wire circuit beyond such an intermediate repeater may or may not carry the superimposed voice circuit.

Repeaters

Meeting, in the general case, the requirement that the physical and carrier

Figure 9. Carrier-frequency switchboard



repeaters be located in the same offices, the attenuation of the repeater sections averages around 20 decibels for the highest carrier frequency. Certain sections may vary widely from this figure but a transmitting level of +10 decibels is rigidly maintained. Figure 8 is a block diagram of a four-wire repeater at an office where both carrier and physical circuits are repeated. The repeating amplifier has a maximum gain of 46 decibels, substantially uniform throughout the range from 400 cycles to 7 kilocycles. This and all of the repeater equipment was designed with a view to the use of a larger spectrum range. In fact, all new repeater equipment installed will be designed to be operable up to 60 kilocycles, dropping perhaps a portion of the extreme low end of the range when high-frequency operation is inaugurated. The amplifier maintains a margin between signal and modulation products of 50 decibels when the aggregate signal level for all channels is +21 decibels. This corresponds to 22 modulated carriers at +10 decibels per channel. It is relatively free from the effects of supply-battery variations, the change in gain being 0.05 decibel per volt. The residual noise of the amplifier, operated on the telegraph battery plant which carries all manner of fluctuating loads from signal circuits to clock circuits and time stamps of heavy drain, is not in excess of −50 decibels.

A line-attenuation equalizing network precedes each repeating amplifier. This, while not adjusted to make the over-all transmission equivalent of the repeater section absolutely flat with frequency, is adequate to prevent overloading of the amplifiers due to a preponderance of energy of any one or group of channels. In general any irregularities in the frequency characteristics of individual repeater sections tend to average out from section to section. The remaining discrepancies of the over-all circuit are taken up in the channel level controls at the terminal.

The design and mounting of the repeater equipment is very similar to that of the channel terminal. One difference is noticeable, however, in the segregation of the apparatus which must be accessible for monitoring and testing from that which need not. The latter is mounted in a remote corner of the office and the former is built into what is known as a carrier-frequency switchboard. In this board are located, in addition to the patch points for the carrier side of the composites and the repeater terminal jacks, all gain controls and all measuring and testing facilities. We have then in the broad picture, the line wires terminating in the regular telegraph switchboard and the carrier circuits and their associated controls in a second board, operated by an especially trained personnel. Figure 9 shows a typical carrier-frequency-board installation. A four-wire repeater switching and control panel occupies a single vertical strip assembly, five inches in width, comprising four rows of jacks and the necessary control and signaling apparatus. Figure 10 is a schematic diagram showing the circuit arrangements of one-half of a carrier board repeater control panel. The equalizing network provided for operation of the pair in the direction opposite to that of the normal assignment comes into play when the pair-reversing patch is made. A common monitoring set serves a number of repeaters. Each repeater is equipped with two amplifier-detectors and associated selectors, and visible and audible alarm apparatus. The selectors operate on both a station and a master call. When a four-wire circuit is idle the terminal repeater attendants can call any or all intermediate repeater stations for trouble location work or for circuit line up. The amplifier-detectors or "monitoring amplifiers" as they are called, operate from a leak circuit on the repeating amplifiers and respond to any frequencies that may be present in the repeater. For normal line-up and regulating work a pilot channel of 1,050 cycles is used. This pilot frequency, applied at the terminals through a skeleton channel terminal set accounts for the principal details by which a terminal repeater differs from an intermediate repeater. At the terminals sending and receiving tuners are used, making the monitoring equipment at these points responsive to but one channel frequency and permitting signal-noise ratio measurements which show the true operating margin of that channel. Intermediate repeaters are not provided with a source of carrier power. The repeater communicates with stations beyond and with the distant terminal in either direction by opening and closing the repeating amplifier output circuit. The response of the repeater monitoring sets to all frequencies facilitates the work of making margin or crosstalk measurements at frequencies other than the normal pilot-channel frequency. The normal gain adjustments of the daily line-up, and routine margin measurements are made on the pilot frequency however. Sufficient spare routes are provided in carrier networks to permit a daily line-up and level check on each. Spare routes are continuously monitored to insure that they are always in readiness to assume a traffic load. In case of line failures, system restoration is made by a terminal-to-terminal patch with very little lost operating time.

A further monitoring convenience, for use on either working or spare circuits, is an amplifier and loud-speaker combination which may be connected to any repeater. One or more of these devices are provided at each repeater station as needed. A multiple push-button circuit connects this equipment to either side of any repeater in order that the attendant may determine in an instant just which circuits are in service and be warned against making any tests which might interrupt a traffic-handling system. A further important use of the loud speaker is in the location of wire trouble. A master call on an idle circuit calls all repeaters. The attendants are asked to connect their speakers and report the firs hit or swing. Through this practice the terminal attendant who

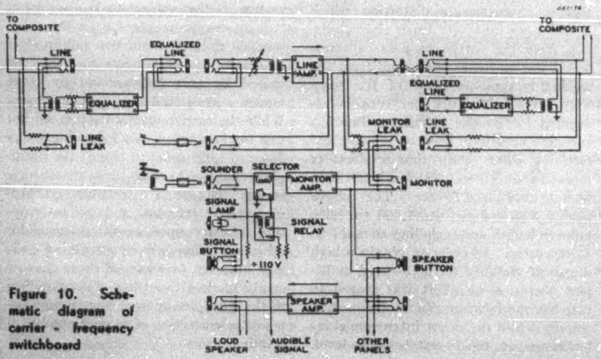


Figure 10. Schematic diagram of carrier - frequency switchboard

may have been warned of a circuit interruption by a swing bell learns almost immediately which repeater section is in trouble.

Incidentally, the use of the spare circuit as an order wire to which the working system is to be moved in case of failure of the normal working circuit is a practice once frowned upon and generally avoided. In carrier working it has been highly satisfactory, and fortunately so, since it is not convenient to have private order or pilot wires extending over the great distances involved between carrier terminals.

Power Level Measurement and Control

Intermediate and terminal repeaters are furnished with a power-level indicating instrument for the measurement of signal and interference levels. This instrument, of the dry-rectifier type, was developed to meet the requirements of high maximum sensitivity and wide range. It is used as a circuit terminating meter rather than as a voltmeter as are many of the similar devices employed in broadcast monitoring. It maintains a purely ohmic impedance of 600 ohms throughout its range. Its accuracy is within ±0.2 decibel from 60 to 10,000 cycles.

An adjustable attenuator located within the instrument extends the range from a full-scale sensitivity of −5.0 decibels to +35.0 decibels and on the lower range it can be read with good accuracy down to −30 decibels. At large repeater stations smaller panel-type instruments are mounted in the carrier switchboard for routine repeater-output-level measurements. These are not adjustable in range and are calibrated only from +5.0 to +15.0 decibels.

By means of the pilot-channel set on spare routes the terminal attendant is able to keep all repeaters properly aligned so as to insure that there will be no repeater overloading when these routes are placed in service. The working systems are kept in proper level alignment by always assigning a manually operated or a single teleprinter circuit to the pilot channel, the 1,050 cycle channel. A duplicate relay-current meter for this channel is mounted in the switchboard where the system level indication is under constant surveillance. The gain of the terminal repeater is adjusted to maintain proper relay operating current on this channel. Only sudden drastic weather changes covering wide areas make it necessary to absorb more than three or four decibels attenuation change at the terminal. This change is not sufficient to cause repeater overloading nor generally to cause excessive bias in channels remote from the pilot frequency. When wider attenuation changes do occur the operating system is moved to a spare circuit and the repeaters are realigned.

Carrier Transmission Standards

It has been determined that a high degree of telegraph transmission efficiency is maintained if the carrier signal-noise margin within the channel bands is not allowed to fall below 30 decibels. This figure is not difficult of attainment for channels above the first. As measured between repeater stations, without benefit of tuners, this sets the requirement at approximately 35 decibels between the signal level and the combined interference, cross talk, and extraneous noise. With repeater section attenuation not exceeding 20 decibels at the highest frequency employed, the cross-talk return loss per repeater section can easily be maintained at 60 decibels or more. With reasonably good pair balances and by insuring that all polar circuits operated on the lead are protected with antinoise filters the line noise can be reduced to a level −45 decibels. The operation of the physical circuits through the composite sets increases the apparent aggregate interference by as much as 5 decibels but the preponderance of energy in this is well below the carrier range. The 450-cycle channel is the only one materially affected by this disturbance.

Telegraph Transmission Standards

On all except the first two channels the total distortion loss at 66 cycles modulation speed does not normally exceed ten per cent. Roughly half of this is characteristic distortion which results from imperfect tuner characteristics, from the carrier by-pass capacitor across the receiving relay, and from the residual-magnetism effect of the relay itself. The other five per cent is accounted for by the extraneous interference, the cross talk between sending and receiving pairs, modulation products of repeaters, and a small amount of direct interchannel interference. The above figures hold for circuits 1,000 to 1,200 miles in length and including as many as 12 repeaters. In order to obtain a high degree of stability for high-speed multiplex operation no effort was spared to keep the modulation effects of repeating amplifiers and the direct interchannel interference at the lowest possible level. Certain other factors such as level changes and occasional cross talk and noise always have their adverse effect on transmission. By keeping the controllable losses to a minimum the highest degree of immunity to the uncontrollable ones is secured. Performance records kept on multiplex circuits assigned to carrier channels indicate the continuity of service to be far better than is obtainable by grounded duplex operation and at least equivalent to that secured by two-wire metallic operation.

The transmission efficiency of the first and second channels is lower than that of the higher channels; first, because of the unfavorable ratio of modulation frequency to carrier frequency; and second, because of a certain amount of interference from the operation of the grounded physical circuits. In addition, the first channel is subjected to a slight handicap due to phase shift between carrier and side-band frequencies. These factors all combine with the result that channel number one while capable of three-printer multiplex working, for absolute stability is normally used in two-printer service. The second is customarily used for three-printer multiplex working.

Maintaining three-printer multiplex operation on the four physical wires of the carrier system, there is little question of the possible economy of abandoning the first channel in favor of slightly improved physical circuit operation. There is, however, no tenable argument for abandoning the physical circuits to secure only a minor improvement in the efficiency of the lower-frequency channels.

Lost time per day on a four-printer multiplex circuit, operating over a carrier system 1,000 miles in length, averages about 12 minutes per day. The carrier system itself is subject to an average of two interruptions per day with a restoration time of about two minutes per interruption. These interruptions are caused by wire failures and by route moves necessitated by various causes. While the carrier system itself is subject to a total outage of only four minutes per day per 1,000 miles of circuit the multiplex is subject to three times that outage because, in case of wire failure synchronism is frequently lost, and each interruption is seized upon as the occasion for other regulating or line-up work. Generally, however, prearranged route changes can be made without loss of synchronism to the multiplex or even interruption beyond the correction of a small number of printing errors.

Conclusions

The employment of carrier in the plant of the Western Union has been a large factor in reducing the new wire construction almost to the vanishing point. A further and perhaps almost as important economy will ultimately be realized in attendance costs of repeaters. Experience indicates that this charge is no more for a carrier repeater than for a single physical repeater handling the same class of service as is assigned to each carrier channel. Economy of repeater office space is another large factor, the carrier repeater requiring less space than a single physical repeater. The loading of cable sections adds to the fixed charges on lines and maintenance costs are increased, but these increases are not large. For long trunk circuits the balance is of course very much in favor of carrier operation and even for circuits of 200-mile length carrier is preferable to new line construction.

Four trunk systems varying in length from 250 to 1,000 miles with a total of 39 channels in operation radiate to the north, south, and west from New York City. In normal assignments 31 of these channels are multiplex operated, with the remainder held in reserve or operated in less important services which may be quickly released for multiplex working.

Numerous single- and double-channel systems operate over short distances where it has been found necessary to secure added facilities. The equipment employed for this class of service differs only in the carrier supply and frequently in the absence of the terminal repeaters.

ASSOCIATE AIEE

CHARLES WINSLOW PALMER
NONMEMBER AIEE

WEN-YUAN PAN
ENROLLED STUDENT AIEE

RESISTANCE-COUPLED amplifiers employing pentode tubes are used more widely than any other type of voltage amplifier for audio frequencies. In spite of this, no method of analysis is available for correctly calculating the complete characteristics of such amplifiers and design procedures ordinarily followed involve considerable cut and try. The present paper presents (1) an analysis taking into account all of the factors of significance in determining the amplification and phase-shift characteristics of ordinary audio-frequency amplifiers employing pentode tubes, together with charts which make it a simple matter to use the analysis; and (2) a systematic procedure for proportioning the coupling network in the plate circuit when the main objective is: (*a*) maximum possible voltage gain, and (*b*) large output voltage.

Calculation of Voltage Amplification

The circuit of a typical resistance-coupled amplifier is shown in figure 1*a*. The magnitude and phase of the amplification obtained with such an arrangement is affected by the coupling network in the plate circuit, by the impedance in the screen circuit external to the tube, and by the impedance between cathode and ground.

If A_0 is the amplification on the assumption that the cathode-ground and screen circuit impedances are zero and the capacitors C_c and C_s in figure 1*a* have no effect, then from conventional amplifier theory[1]

$$A_0 = g_m R \tag{1}$$

where

g_m = mutual conductance of tube,

$R = \dfrac{R_c}{1+\dfrac{R_c}{R_{gl}}+\dfrac{R_c}{R_p}}$ = equivalent resistance formed by coupling resistance R_c, grid-leak resistance R_{gl}, and plate resistance R_p, all in parallel.

The actual amplification will be less than A_0 according to the relation

$$\text{Actual amplification} = A = \alpha\,\beta\,\gamma\,A_0 \tag{2}$$

where

α = factor taking into account the effect of capacitors C_c and C_s in the coupling network in the plate circuit

β = loss of amplification due to impedance in the screen circuit

γ = loss in amplification due to impedance between cathode and ground

Effect of Plate Circuit Coupling Network on Amplification

The factor α that takes into account the effect of the coupling network in the plate circuit upon the amplification can be evaluated with the aid of the equivalent circuit of figure 1*b*. At low frequencies the output falls off and leads in phase because of the loss of voltage in the coupling capacitor C_c, while at high frequencies, the output falls off and lags in phase because of the shunting capacitance C_s. In practical amplifiers the shunting effect of C_s is negligible at low frequencies, while C_c can be assumed to be a short circuit at

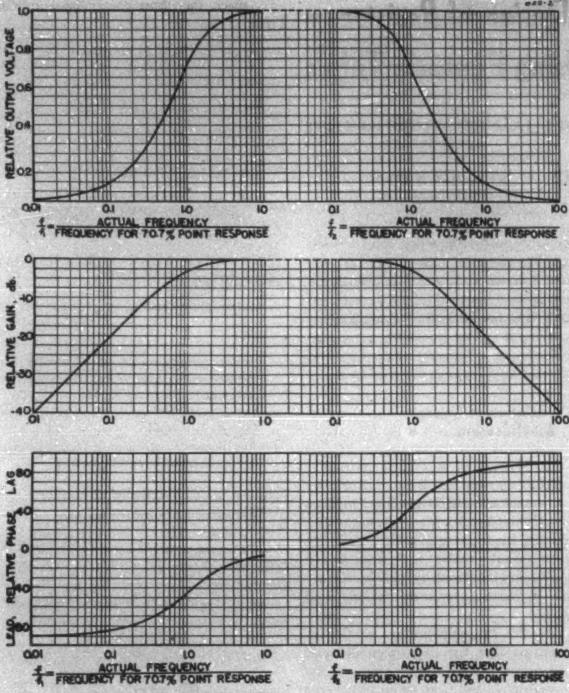

Figure 2. Curves giving effect on amplification of the coupling network in the plate circuit

high frequencies, giving[1]

For low frequencies

$$\alpha = \frac{1}{1 - j\frac{f_1}{f}} \tag{3}$$

For high frequencies

$$\alpha = \frac{1}{1 + j\frac{f}{f_2}} \tag{4}$$

where

f = actual frequency

$$f_1 = \frac{1}{2\pi C_c\left(R_{g1} + \frac{R_p R_c}{R_p + R_c}\right)}$$

= frequency at which the reactance of C_c equals the resistance formed by the grid leak in series with the combination of plate and coupling resistances in parallel

$$f_2 = \frac{1}{2\pi C_s R}$$

f_2 = frequency at which reactance of C_s equals the resistance R as defined in connection with equation 1

Values of α are plotted in figure 2 in a convenient form.

The phase shift and falling off in amplification represented by α is usually taken as the frequency-response characteristic of the amplifier. The actual characteristics may differ appreciably from this at low frequencies because of the impedances in the screen and cathode circuits.

Effect of Impedance in the Screen Circuit

An impedance in the screen-grid circuit such as supplied by the voltage-dropping resistance R_s and the by-pass capacitor C_{sg} in figure 1*a* affects the amplification by the following process: A signal voltage e_s acting between grid and cathode produces variations in screen current as well as variations in plate current. This causes a voltage to be developed between screen and cathode, which affects the plate current and so modifies the gain.

A quantitative analysis can be carried out with the aid of the equivalent screen-grid circuit shown in figure 1*c*. Here the effect on the screen current of the signal voltage e_s applied between control grid and cathode is represented by an equivalent voltage $-\mu_{sg}e_s$ acting in a circuit consisting of the dynamic screen-grid resistance R_{sg} in series with the impedance Z_s in the screen circuit. This equivalent circuit is analogous to the equivalent plate circuit of a triode, with the constant μ_{sg} representing the μ-factor of the screen-grid relative to the control grid with respect to the screen current.[3] The only approximation in this equivalent circuit is that it assumes the screen-grid current is independent of the plate potential, a requirement realized under the practical operating condition of plate current independent of plate potential.

Referring to figure 1*c*, the voltage developed across the impedance Z_s is $-\mu_{sg} \times e_sZ_s/(R_{sg}+Z_s)$. Now this voltage which exists between screen and cathode has the same effect on the plate current as a voltage $[-\mu_{sg}e_sZ_s/(R_{sg}+Z_s)]/\mu_s$ acting on the control grid, where μ_s is the μ-factor of the screen grid relative to the control grid with respect to the plate current. The effect of the impedance in the screen circuit on the gain is accordingly

$$\beta = \frac{e_s - (\mu_{sg}/\mu_s)e_sZ_s/(R_{sg}+Z_s)}{e_s}$$

or

$$\beta = 1 - \left(\frac{\mu_{sg}}{\mu_s}\right)\frac{Z_s}{R_{sg}+Z_s} \tag{5}$$

The ratio μ_{sg}/μ_s appearing in equation 5 represents the relative effectiveness of the control and screen grids on the screen current compared to their relative effectiveness on the plate current. Under the usual pentode operating conditions of plate current independent of plate voltage, this ratio is unity.

In the common case where the impedance in the screen circuit is a resistance-capacitor combination as in figure 1. then for $\mu_{sg}=\mu_s$, equation 5 becomes*

$$\beta = \frac{\frac{K}{1+K} + j\frac{f}{f_s}}{1 + j\frac{f}{f_s}} \tag{6}$$

where

$$K = \frac{R_{sg}}{R_s} = \frac{\left(\text{dynamic resistance of screen-grid circuit of tube}\right)}{\left(\text{voltage dropping resistance in screen circuit}\right)}$$

---

* This assumes that the impedance between the cathode and ground is negligible in comparison with R_s, a condition always satisfied in ordinary designs.

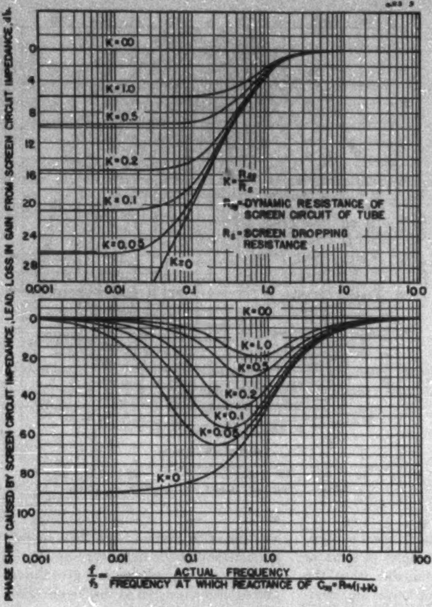

Figure 3. Curves giving effect on amplification of resistance-capacitor combination in screen circuit

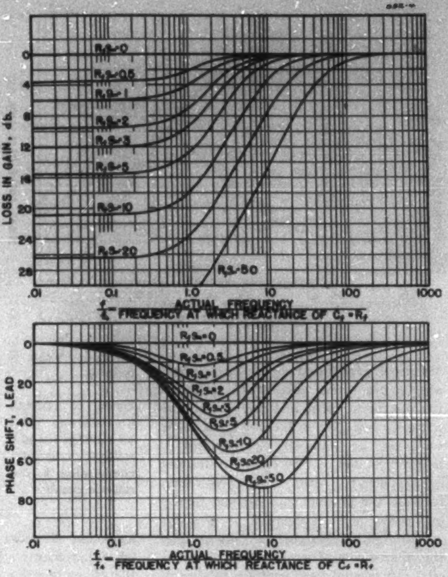

Figure 4. Curves giving effect on amplification of a resistance-capacitor combination in the cathode circuit when the screen impedance has negligible effect

$$f_s = \frac{1+K}{2\pi C_{sg} R_{sg}}$$

= frequency at which the reactance of C_{sg} equals the resistance formed by R_s and R_{sg} in parallel

Values of β are given in convenient form in figure 3 for this case, under the assumption that $\mu_{sg}/\mu_s = 1$.

Examination of figure 3 shows that the resistance-capacitor combination in the screen circuit can cause a large loss in amplification at low frequencies and give rise to considerable phase shift. *In order for these effects to be negligible at a given frequency, it is necessary practically that the reactance of the screen by-pass capacitor* C_{sg} *at this frequency be small compared with the dynamic screen resistance* R_{sg} *of the tube.*

The lack of appreciation of the influence of impedance in the screen circuit on the amplification characteristic is indicated by the fact that information upon the essential constant R_{sg} of the pentode tube is not given in any of the tube data books. The designer must accordingly either measure this constant himself or infer its value from the plate resistance of the same tube operated as a triode. If m denotes the ratio of plate to screen d-c currents for pentode operation then

$$R_{sg} = (1+m)R_p \tag{7}$$

where R_p is the plate resistance of the tube connected for triode operation with the plate current the same as the total d-c space current in pentode operation.

Effect of Bias Impedance on Amplification

Impedance between the cathode and ground such as supplied by R_fC_f in figure 1*a* affects the amplification as a result of the fact that amplified signal currents flow through this impedance. This develops a voltage drop between cathode and ground that is superimposed upon the signal voltage and modifies the amplifier output.

The effect of an impedance Z_f between cathode and ground can be determined as follows:* The current through the impedance Z_f produced by the voltage e_s between cathode and control grid of a pentode tube is $g_m e_s \beta$, which develops a voltage E_f across the impedance Z_f that is $g_m e_s \beta Z_f$. The voltage e_s acting between grid and cathode is related to E_f and the applied signal E_s by the expression $e_s = E_s - E_f$. This gives

$$\frac{e_s}{E_s} = \gamma = \frac{1}{1+g_m Z_f \beta} \tag{8}$$

In the usual case where the impedance Z_f is supplied by a resistance-capacitor combination, as in figure 1*a*, equation 8 can be written

$$\gamma = \frac{1}{1+\dfrac{g_m R_f \beta}{1+j\dfrac{f}{f_4}}} \tag{9}$$

where

$$f_4 = \frac{1}{2\pi C_f R_f}$$

= frequency at which the reactance of C_f equals the resistance R_f

---

* This derivation assumes that the screen grid is bypassed to the cathode so that the signal currents flowing in the screen circuit do not pass through the bias impedance, and so that voltage developed between cathode and ground does not produce voltage between screen and cathode. This is reasonably near the actual case under most conditions, but even when not the case the error will not be important under most conditions.

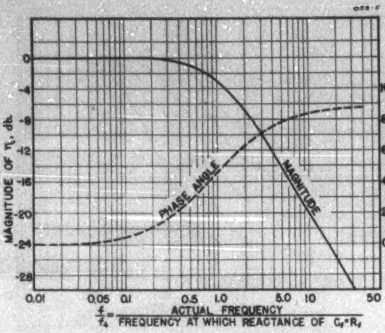

Figure 5. Value of factor η

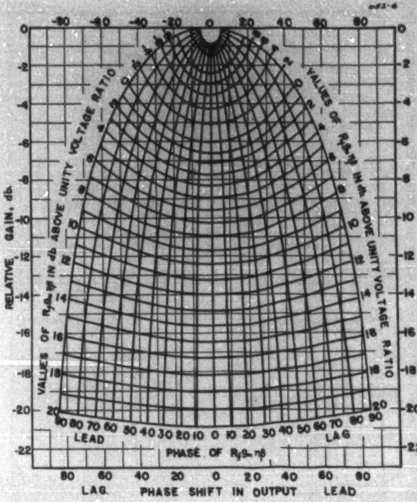

Figure 6 (right). Curves giving effect on amplification of a resistance-capacitor combination in the cathode circuit

Values of γ for the case $\beta=1$ (zero impedance in the screen circuit) are presented in convenient form in figure 4. In the more general case, where $\beta\neq 1$, the value of γ can be obtained with the aid of figures 5 and 6 by first evaluating $\eta=1/(1+jf/f_4)$ from figure 5, then forming the product $g_m R_f \eta\beta$, and finally evaluating γ from figure 6.

Examination of equation 9 shows that the effect of impedance between the cathode and ground in a pentode tube cannot be calculated independently of the impedance in the screen circuit, although this has been the customary procedure in the past.

Discussion

The application of the above analysis to a resistance-coupled amplifier with typical circuit proportions is illustrated in figure 7. Here curve 1 gives the magnitude and phase of the factor α. It represents the amplification characteristic as commonly calculated and is the actual characteristic when the screen and cathode impedances have negligible effect. Curve 2 gives the added phase shift and added loss in gain resulting from the screen impedance. Curve 3 gives the effect of the cathode impedance on the gain and phase shift, and is to be compared with number 4 which gives results that would be obtained by the usual procedure of neglecting the effect of the screen impedance on the action of the cathode impedance. Finally, number 5 gives the actual over-all characteristic, which is a summation of the first three curves. At low frequencies number 5 shows decidedly more falling off in amplification and greater phase shift than number 1.

A full understanding of all of the factors controlling the magnitude and phase shift of the amplification opens the way for designs that will more exactly meet particular requirements. Examples of some of the characteristics obtainable when the screen and cathode impedances are resistance-capacitor combinations of various proportions are given in figure 8. It will be noted that a sharp low-frequency cutoff is obtained by proportioning the screen impedance so that f_3 approximates f_1, and minimizing cathode impedance effects. On the other hand, when minimum phase shift is important, as is the case in amplifiers employing negative feedback, the screen and cathode impedances should both be designed so that f_3 and f_4 are considerably less than f_1.

The formulas that are presented for α, β, and γ have been subjected to extensive experimental checks, both as to magnitude and phase angle. The observed results agreed with the theoretical calculations with an accuracy about the same as that obtained when making triode-amplifier calculations based on the equivalent plate circuit of the triode amplifier.

Design of Amplifiers for Maximum Gain and for Large Output Voltage

In the design of resistance-coupled amplifiers using pentode tubes, the principal problems center about the selection of the proper coupling resistance R_c and the proper d-c plate current. When these are fixed, it is possible to select a combination of bias voltage and screen potential that will give this current, and then to proportion the cathode and screen impedances to develop these voltages and give the required characteristics at low frequencies. The grid-leak resistance is taken as the highest resistance that it is permissible to place in the grid circuit of the succeeding tube, and the coupling capacitor C_c is chosen to give the desired low-frequency response.

In selecting the proper coupling resistance and plate current it is necessary to distinguish between designs in which the principal objectives are: (1) maximum possible voltage gain, and (2) largest possible output voltage without excessive distortion and with at least reasonable gain.

Design for Maximum Voltage Gain

With a given coupling resistance R_c and plate-supply voltage E_B the voltage gain of an amplifier will increase with d-c plate current up to the point where the voltage drop in the coupling resistance is so great that the remaining voltage available for the plate of the tube is insufficient to make the plate current substantially independent of plate voltage. Practically, a slightly larger plate potential is desirable to permit a reasonable tolerance in the coupling resistance R_c. A good practical rule to follow is to consume about 80 per cent of the total voltage in the coupling resistance.

With a specified voltage drop in the

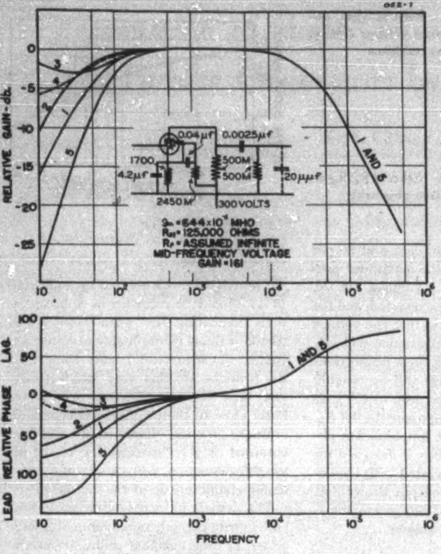

Figure 7. Characteristics of actual amplifier

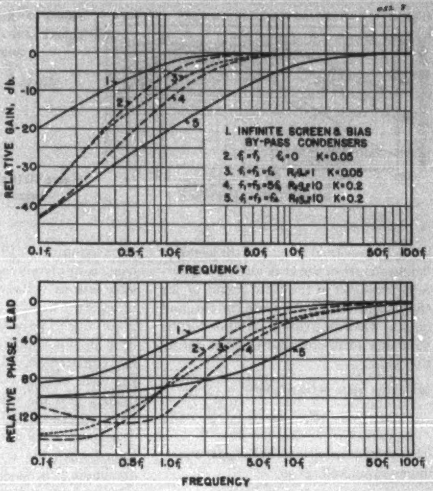

Figure 8. Typical low-frequency amplification characteristics obtainable with different resistance-capacitor combinations in screen and cathode

coupling resistance R_c, maximum gain is obtained when the coupling resistance has a definite relation to the grid-leak resistance. To obtain this relation, one first rewrites equation 1 considering the plate resistance R_p so great as to have negligible effect, an assumption very closely realized in practice.* This gives

$$A_0=g_m\frac{R_cR_{gl}}{R_c+R_{gl}} \tag{10}$$

One also has

$$\text{Plate current}=i_p=k\left(e_g+\frac{e_{sg}}{\mu_s}\right)^n \tag{11}$$

$$g_m=\frac{di_p}{de_g}=nk\left(e_g+\frac{e_{sg}}{\mu_s}\right)^{n-1} \tag{12}$$

$$\text{Voltage drop in coupling resistance}=E_d=i_pR_c \tag{13}$$

In these equations n and k are constants, e_g and e_{sg} are the direct voltages applied to the control and screen grids respectively, and μ_s has the same meaning as in equation 5. Substitution of (12) into (10), elimination of (e_g+e_{sg}/μ_s) by (11), and using (13) to eliminate i_p gives

$$\text{Amplification}=A_0=nk^{\frac{1}{n}}E_d^{\frac{n-1}{n}}R_g^{\frac{1}{n}}\frac{(R_c/R_{g1})^{1/n}}{1+\dfrac{R_c}{R_{g1}}} \tag{14}$$

Differentiation of A_0 with respect to R shows that

$$R_c\text{ for maximum gain}=\frac{R_{gl}}{n-1} \tag{15}$$

Equations 14 and 15 express a number of important properties of resistance-coupled amplifiers using pentode tubes. The exponent n in these equations can be expected to have values of the order of 1.5 to 2.25, with values of 2 or a little less typical for the usual operating conditions where the plate current is somewhat less than the rated value. Accordingly, the optimum coupling resistance R_c is roughly equal to the grid-leak resistance R_{gl} although the gain is not critical with respect to the ratio R_c/R_{gl}, as shown in figure 9.

The proper design procedure to obtain maximum gain is to make $R_c=R_{gl}$ and then check f_2 to see if the high-frequency response is satisfactory. If the high-frequency response is poorer than desired, R_c is lowered as necessary, and the resulting loss in gain accepted as the price paid to obtain the desired high-frequency characteristics.

Design for Large Voltage Output

The maximum output voltage is limited on the negative half cycle of the applied signal by the fact that the instantaneous plate current can never be less than zero, and on the positive half cycle by the fact that the instantaneous potential at the plate of the tube (direct voltage at plate minus peak a-c output voltage) must not be so low as to cause the plate current to cease to be independent of plate potential. With a given ratio R_c/R_{gl}, maximum output voltage occurs when these two limits are simultaneously reached with a sine-wave signal. The relations involved are approximated by the following analysis. Let

E_B = plate-supply voltage

$$r=\frac{\begin{pmatrix}\text{lowest plate potential at which plate}\\ \text{current is independent of plate voltage}\\ \text{when plate current is twice the d-c}\\ \text{value}\end{pmatrix}}{E_B}$$

$E_d=i_pR_c$ = direct-voltage drop in coupling resistance

i_p = d-c plate current

If the instantaneous plate current is to

---

* This approximation can be avoided by interpreting R_{gl} in equations 10, 14, and 15 to be the resistance formed by the plate resistance of the tube in parallel with the actual grid-leak resistance. The results then obtained are correct to the extent that the combined resistance varies much more slowly with plate current than does the transconductance. These remarks also apply to equations 16 and 17 and the related text.

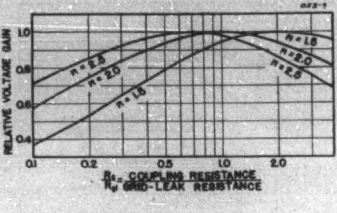

Figure 9 (left). Relative gain obtained with constant voltage drop in coupling resistance

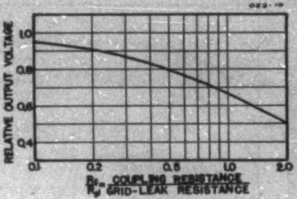
Figure 10 (right). Effect of R_c/R_{gl} on output voltage obtainable



swing from normal to zero on the negative half-cycles, then the peak alternating current developed in the plate circuit of the tube is equal to the d-c plate current, and one can write the following relation for the minimum plate potential reached during the cycle:

Minimum plate potential =

$$E_B - E_d - i_p\frac{R_cR_{gl}}{R_c+R_{gl}} = rE_B$$

This gives the voltage drop E_d for maximum output voltage as

$$E_d = (1-r)\left(\frac{1+\frac{R_c}{R_{gl}}}{2+\frac{R_c}{R_{gl}}}\right)E_B \qquad (16)$$

The corresponding output voltage is $\frac{R_{gl}R_c}{R_c+R_{gl}}i_p$, or

$$\text{Maximum output voltage} = \frac{(1-r)}{2+\frac{R_c}{R_{gl}}}E_B \qquad (17)$$

This equation shows that the relative output voltage increases as R_c/R_{gl} is reduced, with the exact relation given by figure 10.

The practical procedure for obtaining maximum output voltage is to select coupling resistance R_c that makes R_c/R_{gl} a reasonable compromise between maximum gain and maximum power output. Usual values are in the range 0.2 to 0.5, corresponding to 91 per cent and 80 per cent, respectively, of the maximum possible output voltage. A value of r of the order of 0.1 to 0.2 is then assumed, and the plate current adjusted so that the voltage drop in this coupling resistance will satisfy equation 16. With these proportions the peak output voltage will be roughly $0.35E_B$, and the voltage drop in the coupling resistance will approximate 0.5 E_B.

A comparison of the amplification obtained when the amplifier is designed for maximum gain as contrasted with the design for large voltage output shows that in the former case the voltage amplification is about one-third greater.

Effect of Plate-Supply Voltage and Grid Leak Resistance on Amplification

Examination of equation 14 shows that for a fixed value of R_c/R_{gl} the gain is proportional to the voltage drop $E_d^{(n-1)/n}$ (and hence to $E_B^{(n-1)/n}$), and also to $R_{gl}^{1/n}$. In practice this means that the amplification obtainable from a resistance-coupled amplifier, irrespective of whether designed for maximum gain or large output voltage, can be expected to be proportional to something between the square root and cube root of the plate-supply voltage, and between the square root and two-thirds power of the grid-leak resistance.

Discussion

The relations represented by equations 14–17 should be regarded as approximations indicating the main factors and trends without giving highly accurate answers. Experimental results show that the formulas do this very satisfactorily, and that the quantitative results are fairly close to those considered typical in ordinary practice. Exact results could be obtained only by specification of the allowable distortion, and a study of the dynamic characteristic of the amplifier.

The designs for resistance-coupled amplifiers with pentode tubes commonly suggested in tube manuals[3] approximate the proportions recommended here for large output voltage, and lead to allowable output voltages that are generally within ten per cent of those calculated by equation 17.

Determination of Short-Circuit Torques in Turbine Generators by Test

E. C. WHITNEY
ASSOCIATE AIEE

H. E. CRINER
NONMEMBER AIEE

THE consideration of short-circuit stresses in turbine-generator shafts and frames must be preceded by a knowledge of the developed electrical torque. The theoretical work for this subject has been done by Kilgore and Stone, and Nickle, Pierce and Henderson. As far as is known there have been no extensive measurements of short-circuit torques on modern turbine generators. The object in performing these experiments was to obtain data to check previous equations derived from theoretical considerations and, if necessary, make revisions.

Description of Equipment and Test

A 3,600-rpm 12,500-kva 80 per cent power-factor 13,800-volt three-phase 60-cycle turbine generator was used in making the tests. This machine was of standard construction except that the stator core was flexibly supported with respect to the frame. The machine was driven as a synchronous motor at speeds slightly above 60 cycles. Immediately preceding the short circuit, the generator was disconnected from the power supply and the short circuit applied as it coasted down through 60 cycles. This was done to eliminate driving equipment consisting of another rotor mass and connecting shaft which would have introduced unnecessary complications in the analysis of the measured torques. The currents and voltages were measured in the usual manner and the torques by a strain gauge, which will be described later. The short circuit was applied with a solenoid-operated three-phase oil circuit breaker of suitable rating. The breaker was closed by relay action and was set to open approximately 16 cycles after closing.

The tests were made with various types of short circuits including three phase, line to line, and line to neutral at both 75 per cent and 100 per cent voltage. The line-to-neutral short circuits were taken with two different values of reactance in the neutral.

The accelerometer for measuring the shaft torque is shown in figure 1 and is fundamentally the same as that described in Mr. Penney's paper.[1] The torque rod of the instrument is fastened at the rear to the case of the accelerometer and at the front end to the flywheel. The fundamental mode of operation of the instrument is as follows: When a torque accelerates the generator rotor there is a torque imposed on the flywheel which is proportional to the acceleration. This displaces the flywheel relative to the case. The displacement is limited by the torque rod so that it is proportional to the torque applied to the rotor. The displacement is measured by an ordinary magnetic strain gauge. The armature of the strain gauge is fastened to the flywheel and the pole pieces to the accelerometer case. There is no damping arrangement provided in this instrument so that the natural-frequency vibration of the flywheel appears on the torque record. However, the ratio of the natural frequency of the accelerometer to the electrical torques in the machine is sufficiently high so that little difficulty is encountered in interpreting the record.

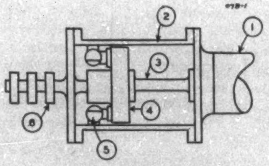

Figure 1. Accelerometer

1—Generator shaft to which accelerometer is fastened
2—Case of accelerometer
3—Torque shaft
4—Flywheel
5—Magnetic strain gauge
6—Collector assembly

The strain-gauge circuit was modified so that it contained two gauges and an electrical filter, as shown in figure 2. The two strain gauges were connected so that the torsional sensitivity was doubled, and lateral movement was cancelled. The filter removed the power input frequency from the record. This circuit has been extensively used in other places and is described at some length in previous papers.[2]

Figure 2. Strain-gauge circuit

In order to eliminate the need of measuring extremely small displacements, the natural period of the accelerometer was set at 270 cycles per second and the magnification of the various components of the records taken into account in the calibration.

Since it was impossible to prevent other portions of the instrument besides the torque rod from deflecting, it was considered necessary to calibrate this instrument dynamically. A setup was made (see figure 3) whereby an oscillatory acceleration could be applied to the rear end of the accelerometer case. Oscillograph records were taken of the flywheel movement (see figure 4) and at the same time the vibration amplitude at the flange of the case was measured. With these data it was

Line to line to ground	$T=\frac{e_0^2}{3(X_0X_d''+X_2X_d''+X_0X_2)}\times$ $\sqrt{\left(X_2^2+\frac{X_0X_2}{2}+X_0^2\right)\left[2\sin^2\theta\cos^2 m+\sin^2(\theta+m)\right]}FA\sin(\omega t+\theta)+$ $\frac{e_0^2X_0}{X_0X_d''+X_d''X_2+X_0X_2}F^2\sin 2(\omega t+\theta)+\left(\frac{X_0e_0}{X_0X_d''+X_d''X_2+X_2X_0}\right)^{1.8}2(R_2-R_1)F^{1.8}+$ $\left[\frac{e_0\sqrt{X_2^2+\frac{X_1X_0}{2}+X_0^2}}{3(X_0X_d''+X_d''X_2+X_0X_2)}\right]^{1.8}\frac{R_2-R_1}{\sqrt{2}}A^{1.8}+\left[\frac{e_0\sqrt{X_2^2+\frac{X_2X_0}{2}+X_0^2}}{X_0X_d''+X_d''X_2+X_0X_2}\right]^2\times$ $\left(\frac{R_1+R_e}{3}\right)F^2[1-\cos 2m\cos 2(\omega t+\theta)]$ where $m=30°+\tan^{-1}\frac{0.866X_0}{0.5X_0+X_2}$, θ = angle of the voltage wave of the unshort-circuited phase at the instant of short circuit $A=\epsilon^{\frac{-t}{T_a}}$ $F\approx\frac{X_d''(X_2+X_0)+X_2X_0}{X_d'(X_2+X_0)+X_2X_0}\epsilon^{\frac{-t}{T_{d0}}\frac{X_d'(X_2+X_0)+X_2X_0}{X_d(X_2+X_0)+X_2X_0}}+\frac{(X_d'-X_d'')(X_2+X_0)}{X_d'(X_2+X_0)+X_2X_0}\times$ $\epsilon^{\frac{-t}{T_d''}\left(\frac{X_d''}{X_d'}\right)\left(\frac{X_d'(X_2+X_0)+X_2X_0}{X_d''(X_2+X_0)+X_2X_0}\right)}$

possible to calculate the torque imposed on the flywheel and relate it to the amplitude measured from the oscillogram. In order to check and correlate the sensitivity of the instrument between setups, static torque versus oscillograph deflection records were taken and are plotted in figure 4. The 11 per cent difference shown is due to the aforementioned displacement of case, gauge mounting, etc., and corresponds to values calculated for these displacements. The actual use of this calibration is described in the appendix.

Calculation of Electrical Air-Gap Torque During Short Circuit

It is known that in all machines high alternating torques are developed during short circuit. It is also known that during some types of short circuits the machine seems to "load up" during the first few cycles rather than dump load as might be expected. The calculation of the alternating components of torque caused by the reaction of the fundamental fluxes and currents in the machine during short circuit is handled in a very thorough manner by Nickle, Pierce, and Henderson.[5] These component values checked the test values very closely. It appears from this test that these calculated values tend to be between five and ten per cent high due to flux distortion and several other factors. However, this accuracy can be considered very good for this type of calculation, especially since it tends to be pessimistic. The tendency of a machine to "load up" during short circuit is due to loss torques, which have been neglected by most previous authors. Mr. Kilgore in a later paper[4] attempted to account for the

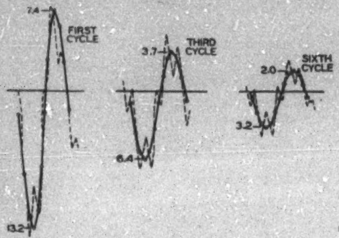

Figure 5. Three-phase short-circuit torques

loss torques. However, he assumed that every loss in the machine resulted in torque and with this in mind arrived at an equation which gives results which are much too large. The loss or unidirectional torque is of prime importance to the central-station engineer in the calculation of stability. There are three types of unidirectional torque, namely, a steady torque, a displaced rated-frequency component, and a displaced double-frequency component. The rated-frequency component of loss torque appears to be negligible in all types of short circuits and consequently will be disregarded.

Since this paper is primarily interested in turbine generators, all equations will be given as for turbine generators. For modifications to suit salient-pole machines, the fundamental flux components (sin ωt and sin $2\omega t$) may be modified in line with Nickle, Pierce, and Henderson's paper[3] to take care of higher order harmonics due to saliency.

It will be noted that in the equations presented in table I, the torque does not start from zero. This is due to several neglected components which die out very rapidly.

It will also be noted in table I that several of the loss torque components vary as the 1.8 power of the current. This has been shown to be approximately correct for a turbine generator.[3] For salient-pole machines this exponent will be 2.

The approximations for the factor F found in the equations are the result of neglecting the sustained short-circuit current and result in only slightly lower torque after eight or nine cycles. Since few torque calculations extend beyond ten cycles, this approximation is justified.

The mechanical design engineer will be interested chiefly in the alternating torques, while the stability engineer will be interested in the unidirectional components. It will be noted that the $(1-\cos 2\omega t)$ terms are unidirectional, but for stability calculations the $\cos 2\omega t$ may be omitted.

It is believed the above equations present a good engineering calculation for the torques encountered in a turbine generator under short circuit. The oscillograms shown in figures 5, 6, and 7 have the test record plotted in dotted lines, while the calculated torque is plotted in solid lines to the same scale. The peak torques are marked in terms of per unit torque based on the three-phase kilovolt-ampere rating of the machine, which in this case is 12,500 kw.

The natural frequency of the accelerometer adds to some peaks while it apparently detracts from others. Considering this when observing the oscillograms, the agreement between test and calculated peaks is better than ten per cent in the three-phase and the line-to-line cases. The line-to-neutral short circuits do not agree quite so well in the case of a reactor in the neutral when the current is asymmetrical. The calculated sin ωt term appears to be about 30 per cent larger than the test value indicates. However, the sin $2\omega t$ term agrees very well.

The rated voltage values of the test machine reactances are listed in table II. These reactances are slightly lower than the average machine of this rating, resulting in large currents during short circuit. The test currents and torques for various types of short circuits are also tabulated.

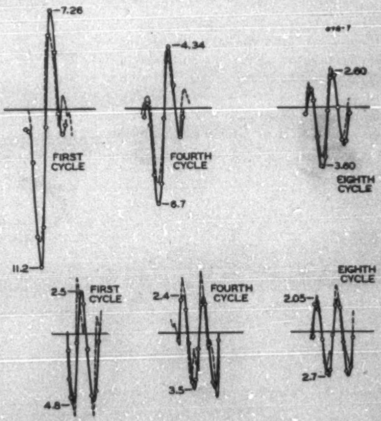

Figure 7. Line-to-neutral short-circuit torques with 0.357 ohm reactance in neutral

Table II

Constant	X_d''	X_d'	X_d	X_2	X_0	T_d''	T_d'	T_{d0}	T_a
Test Value	0.087	0.118	1.20	0.087	0.010	0.040	0.48	4.88	0.108

Type of Short Circuit	Per Unit	Scalar
Three phase		
(*A*). Peak current recorded in worst phase	22.3	16,500 amp
(*B*). Average rms instantaneous symmetrical current	11.5	6,000 amp
(*C*). Peak torque	13.2	165,000 kw
Line to line		
(*A*). Current totally asymmetrical		
1. Peak measured current	22.0	16,300 amp
2. Rms symmetrical instantaneous current	11.8	6,180 amp
3. Peak torque	16.8	210,000 kw
(*B*). Current practically symmetrical		
1. Peak measured current	11.5	8,500 amp
2. Rms symmetrical instantaneous current	10.2	5,300 amp
3. Peak torque	7.6	95,000 kw
Line to neutral with 0.148 ohm or 0.0097 per unit reactance in neutral		
(*A*). Current totally asymmetrical		
1 Peak measured current	28.1	20,800 amp
2. Rms symmetrical instantaneous current	15.0	7,850 amp
3. Peak torque	13.0	162,500 kw
(*B*). Current practically symmetrical		
1. Peak measured current	15.3	11,300 amp
2. Rms symmetrical instantaneous current	9.2	6,800 amp
3. Peak torque	5.7	71,300 kw

All data are for 100 per cent voltage short circuits with comparisons for various conditions of asymmetry for the single-phase cases.

Conclusion

The torque discussed in this paper is the electrical torque developed at the air gap of the machine and is not the torque at the coupling or that transmitted to the foundation. The torque in couplings, shafts, and foundations must be calculated from a consideration of the masses and mechanical spring constants involved.

Previous published equations for the torque developed in a synchronous machine during short circuit have been almost entirely theoretical. As far as is known, the test results of this paper constitute the first experimental check of the theoretical equations as applied to a turbine generator. The test results show that the alternating components of torque exist in substantially the same magnitude as calculated theoretically. The test results also indicate the existence of loss torques of a magnitude sufficient to require a method of calculation superior to any heretofore available. It is believed that the terms added to previous torque equations by the authors represent the retardation torques quite accurately.

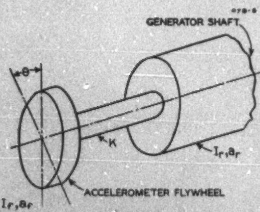

Figure 8. Analytical diagram of accelerometer

Appendix I

An analysis of the accelerometer is as follows:

I_r = moment of inertia of the rotor
a_r = angular acceleration of the rotor
K = spring constant of torque rod
I_f = moment of inertia of flywheel
a_f = acceleration of flywheel. $a_f'' = \frac{d^2a_f}{dt^2}$
θ = angular displacement of flywheel from the equilibrium position

$$\theta'' = \frac{d^2\theta}{dt^2}$$

$$p^2 = \frac{K}{I}$$

See figure 5.

The acceleration of the rotor is equal to the acceleration of the flywheel plus the first derivative of the rate of increase of the angle θ.

$$a_r = a_f + \frac{d^2\theta}{dt^2} \qquad (1)$$

The torque in the torque shaft equals the torque due to the flywheel acceleration.

$$Ia_f = T = K\theta$$

differentiating

$$I\frac{d^2a_f}{dt^2} = K\frac{d^2\theta}{dt^2}$$

or

$$\theta'' = \frac{I}{K}a_f''$$

substituting in (1)

$$a_r = a_f + \frac{I}{K}a_f''$$

rewriting in the usual form

$$a_f'' + \frac{K}{I}a_f = \frac{K}{I}a_r$$

or

$$a_f'' + p^2a_f = p^2a_r \qquad (2)$$

The rotor acceleration may be expressed in two forms:

$$a_r = \Sigma A_0\epsilon^{-\beta t} + \Sigma A_1\epsilon^{-\alpha t}\sin(\omega t + \theta) \qquad (3)$$

where β, α, A_1, ω, and θ may have at least two different values.

The complementary function of the solution of (2) will have the following form:

$$a_f = C_1\cos pt + C_2\sin pt$$

so that the rotational velocity of the free vibration will have the value p.

The above expression will not be considered after this for the reason stated in the discussion of the instrument.

The particular solution will be the sum of the solutions for each component given in (3). The particular solution for the form given in the first member of (3) will be

$$a_f = A\epsilon^{-\beta t}\frac{1}{\left(\frac{\beta}{p}\right)^2 + 1} \qquad (4a)$$

For the second form it will be

$$a_f = \frac{p^2A_1\epsilon^{-\alpha t}[(\alpha^2 + p^2 - \omega^2)\sin(\omega t + \theta) + 2\omega\alpha\cos(\omega t + \theta)]}{(\alpha^2 + p^2 - \omega^2)^2 + 4\omega^2\alpha^2} \qquad (4b)$$

(4*b*) may be simplified to

$$a_f = \frac{A_1\epsilon^{-\alpha t}\sin(\omega t + \theta + \phi)}{\sqrt{\left(\frac{\alpha}{p}\right)^2 + 1 - \left(\frac{\omega}{p}\right)^2 + \left(\frac{2\omega\alpha}{p^2}\right)^2}} \qquad (4c)$$

where

$$\phi = \tan^{-1}\frac{2\omega\alpha}{\alpha^2 + p^2 - \omega^2}$$

Now in this particular case α and β are small compared to ω and p. Therefore, a further simplification can be made in the above equations which introduces negligible errors. The amount of error may be ascertained by substitution of proper values in (5*a*) and (5*b*) and comparing the results.

The simplified equations will be

$$a_f = A\epsilon^{-\beta t} \qquad (5a)$$

$$a_f = A\epsilon^{-\alpha t}\sin(\omega t + \theta)\cdot\frac{1}{1 - \left(\frac{\omega}{p}\right)^2} \qquad (5b)$$

The largest effective α or β in this case is about 25, $\omega = 120 \times 2\pi$, $p = 274 \times 2\pi$; substituting in the above equations.

$$\left.\begin{array}{l}\text{From (4}a\text{), } a_f = 0.991A\epsilon^{-\beta t}\\ \text{From (5}a\text{), } a_f = 1 \times A\epsilon^{-\beta t}\end{array}\right\}\text{ error 1 per cent}$$

$$\left.\begin{array}{l}\text{From (4}c\text{), } a_f = 1.22A\epsilon^{-\alpha t} \times \sin(\omega t + \theta)\\ \text{From (5}b\text{), } a_f = 1.236A\epsilon^{-\alpha t} \times \sin(\omega t + \theta + \phi)\end{array}\right\}\text{ error } 1^1/_2\text{ per cent}$$

From (4*c*), $\phi = \tan^{-1} 0.002$
Therefore ϕ is assumed 0

This can only be done if β and α are small. The error will increase rapidly with larger values.

Calibration Relationships

Refer to discussion on instrument calibration

T_f = torque on the flywheel during calibration
r = radius of flange
R = one-half of measured amplitude
$w_c = 2\pi f_c$, where f_c is the vibration frequency secured from the calibration record
T_0 = value from calibration curve
δ_0 = value from calibration curve
δ = measured value of deflection from record

It may be deduced from (5*b*) that

$$T_f = \left[\frac{R\omega_c^2 \sin \omega t}{1-\left(\frac{\omega_c}{p}\right)^2}\right]\frac{I_f}{r}$$

T_f was plotted against δ_0 to secure curve of figure 4.

Calibration Constants Applied to Test Data

It may be shown that

$$\delta = \left[\frac{1}{1-\left(\frac{\omega}{p}\right)^2}\cdot\frac{I_f}{I_r}\cdot\frac{\delta_0}{12T_0}\right]T_r$$

In order to transfer T_r into the ordinarily used T_{el} or times rated torque units, it is only necessary to multiply by 0.511/rated kw so that

$$\delta = \left[\frac{1}{1-\left(\frac{\omega}{p}\right)^2}\cdot\frac{I_f}{I_r}\cdot\frac{\delta_0}{12T_0}\cdot\frac{\text{rated kw}}{0.511}\right]T_{el}$$

For this particular case

$\delta_1 = 0.196T_{el}'$—unidirectional components
$\delta_2 = 0\ 206T_{el}''$—60-cycle components
$\delta_3 = 0\ 243T_{el}'''$—120-cycle components

Appendix II

The terms which have been added to previous torque equations by the authors have been derived from theoretical considerations, although it is realized that a good many small factors are omitted. The factors considered include the following: First, the torque caused by the rotor cutting the flux trapped in the stator winding. Second, the torque caused by I^2R, where R includes the positive-sequence resistance and external resistance. Third, the torque caused by the negative-sequence component of the stator current in the case of single-phase short circuits.

When flux is trapped in the stator winding at the instant of short circuit, the flux remains stationary in physical position while the rotor continues to rotate. In principle this is exactly the same as a locked-rotor starting condition with sufficient current in the stator to produce a flux equal to that trapped in the stator winding. The resultant torque equals

$$\left(\frac{e_0}{Z}\right)^{1.8}R_{rs}A^{1.8}$$

where Z is the impedance for the particular short-circuit condition and R_{rs} is the rotor resistance component of the starting impedance. Since* R_{rs} is very nearly equal to $\frac{R_2-R_1}{\sqrt{2}}$* this substitution is made to eliminate unnecessary additional constants. This loss in a turbine generator varies approximately as the 1.8 power of the current.[6]

The second component is the loss due to positive-sequence resistance. The d-c component of stator current is neglected because this current is the result of changing stored magnetic energy and results in no direct torque. Hence, only the alternating current is considered. The resultant equation is

$$\left(\frac{e}{Z}\right)^2(R_1+R_e)F^2$$

for a three-phase short circuit. For the single-phase case this is a pulsating unidirectional double-frequency loss so that this term becomes

$$\left(\frac{e}{Z}\right)^2(R_1+R_e)\frac{[1-\cos 2(\omega t+\alpha)]}{2}F^2$$

The third component of unidirectional torque is the result of the negative-sequence component of stator current (I_2) squared times the negative-sequence resistance (R_2). It is a well-known fact that when negative-sequence voltage is applied to the armature of a machine only one-half the total loss appears as input to the armature and the other half appears as torque. However, in the case of a single-phase short circuit all the loss appears as torque due to transformer action between the sequences. Thus, the loss torque due to negative-sequence current becomes $I_2^{1.8}2R_2$. This loss also varies approximately as the 1.8 power of current. In the equations of table I, all current terms are converted to a per unit equivalent three-phase current. Since the loss due to R_1 has been taken care of in another component, this component becomes

$$I_2^{1.8}2(R_2-R_1)F^{1.8}$$

which for the line-to-line case is

$$\left(\frac{e_0}{X_2+X_d''}\right)^{1.8}2(R_2-R_1)F^{1.8}$$

List of Symbols

All units are in per unit terms.

T = per unit electrical torque based on rated kilovolt-amperes
X_d'' = subtransient reactance
X_d' = saturated transient reactance
X_d = synchronous reactance
X_2 = negative-sequence reactance
X_e = external reactance
X_0 = zero-sequence reactance
T_{d_0} = open-circuit transient time constant
T_d' = transient time constant
T_d'' = subtransient time constant
T_a = armature time constant
t = time after application of short circuit
e_0 = per unit voltage just previous to short circuit
ϵ = 2.718 = base of natural logarithms
R_1 = positive-sequence resistance
R_2 = negative-sequence resistance
R_e = external resistance
R_{rs} = rotor resistance component of the starting impedance

Application of and Operating Experience With Hydrogen-Cooled Synchronous Condensers and Alternators

I. Introduction

UNTIL about ten years ago the only cooling medium utilized for electrical rotating machinery was air. Obviously this was occasioned not by the fact that air has any particularly suitable characteristics but because it is the daily common surrounding medium which, of necessity, must be used for open-type machinery. Before that time, the need for construction of machines of constantly increasing size and speed had brought about the development of closed systems of ventilating. In these, facilities had been provided for conditioning the cooling air, but this had been primarily for the purpose of removing dust particles. The elimination of the particularly objectionable oxygen had not been attempted although for some time inert gas had been used in transformers to prevent oxidation of oil or insulation.

Since the use of any medium other than air necessitates a gastight enclosure, it is desirable to use that particular gas or mixture of gases, which offers the most advantages to outweigh the fact that more expensive construction is required. The desirability of using hydrogen for this purpose was first suggested by Doctor W. R. Whitney of the General Electric Company about 18 years ago, and as a result a large amount of study and numerous tests were made to determine the advantages of employing this particular gas. The superiority of hydrogen was definitely indicated especially in the case of large high-speed alternators. The difficult problem of a simple and reliable shaft seal, as well as the ability of designers to utilize air cooling satisfactorily on machines required by the power industry, delayed the use of hydrogen in generators until several years ago.

In the meanwhile attention was directed to the hydrogen-ventilated synchronous condenser, and in 1928 two such machines were placed in service, one of which was the 20,000-kva unit at the Turner station of the Appalachian Electric Power Company. This was followed at intervals, by seven others on the systems with which the authors are associated, comprising in all a combined capacity of 161,000 kva. The successful operation of these machines led to the installation in 1937 of a 50,000-kva hydrogen-cooled generator at Logan, W. Va. This was followed by a 66,667-kva generator placed in service the early part of 1939. An additional condenser was placed in operation in July 1939; still another in November 1939, and two more generators are in process of installation and will go into service early in 1941, making a combined total of 432,000 kva on the American Gas and Electric Company systems.

There has thus been obtained an experience with hydrogen, on the systems with which the authors are associated and under their operating supervision, of combined continuity and on size and rating of equipment far greater than has been obtained anywhere else. It is the purpose of this paper to describe that experience and indicate its bearing on the design, application, and operation of hydrogen-cooled rotating equipment.

II. The Basic Problems Presented by Hydrogen Cooling

Before proceeding with a description of the installations involved, it may be desirable to review briefly the advantages of hydrogen and to discuss the basic problems involved in its application.

A. ADVANTAGES OF A HYDROGEN ATMOSPHERE

The basic advantages which are obtained because of the characteristics of hydrogen have been covered elsewhere.[1-5] In briefest summary they are: low density, high thermal conductivity, high forced heat convection, prevention of detrimental effect from corona, no combustion or oxidation, cleanliness of atmosphere, ease of adaptation to outdoor service, and quiet operation.

B. BASIC PROBLEMS IN DESIGN, APPLICATION, AND OPERATION OF HYDROGEN-COOLED EQUIPMENT

The basic problems involved in the design, application, and operation of hydrogen-cooled rotating machinery, and particularly synchronous condensers* are, in order of importance, as follows:

1. *Gastight and Explosionproof Outer Shell*

While the possibility of an explosion is extremely remote, it is nevertheless necessary to take every reasonable precaution to minimize the effect of such an occurrence and therefore an explosionproof shell (that is, a shell which will not blow apart) consisting of boiler plate has been employed from the first designs on. In general, the ends of the shell are closed by means of two dome-shaped end bells, with the joints gasketed to prevent leakage of hydrogen. In most cases, castings, which are frequently porous, have been eliminated. This has helped in obtaining a gastight construction. The problem of welding these shells has been a difficult one particularly from the standpoint of gas leakage. The carrying through the shell of the miscellaneous oil, water, and gas piping as well as electrical connections has been solved quite satisfactorily. Continued study and design changes for the purpose of decreasing gas leakage at pressures of 15 pounds per square inch or more have been required to obtain the maximum benefit from hydrogen cooling.

2. *Water Cooling*

The development of internal surface coolers of utmost reliability was essential, since the coolers are ordinarily inaccessible. It was desirable to install the coolers in such a manner as to permit periodic cleaning without removal of gas from the machine. As far as operation is concerned this also introduces the problem of a suitable and adequate water supply and some system for cooling the water such as a spray pond or cooling tower. Water cooling of the bearings also introduced some difficulties such as adequate flow to the cooling coils, and insulation of

* The problem of shaft sealing applicable to generators is discussed later in section IX.

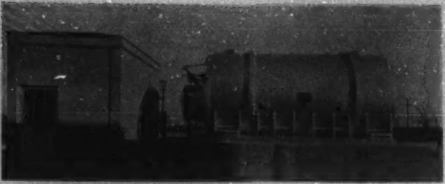

Figure 1. 36,000-kva 11,500-volt hydrogen-cooled synchronous condenser at the Fostoria station of The Ohio Power Company

the piping to prevent the flow of shaft currents.

3. *Collector Compartment, Rings, and Brushes*

For all synchronous condensers, excitation has been obtained externally from motor-driven or electronic exciters. The problem of finding the proper design and material for brush rigging, brushes, and collector rings for the fields of the condensers suitable for operation in hydrogen, was one that had to be determined largely by actual experience. The ventilating of the collector compartment, and the accumulation of brush dust, brought up the questions of how often to clean the compartment and how to prevent any appreciable amount of this dust from being carried into the stator and rotor.

4. *Provision for Maintenance and Inspection of Condensers*

In general, manholes have been provided for inspection of the interior and for minor repairs, including bearing inspection or replacement. Provision of overhead lifting facilities for complete disassembly of the machine has been taken care of more simply on the later installations. For periodic inspection of the collector compartment, various types of seal have been developed, with experience indicating what changes were desirable.

5. *Hydrogen Accessory Equipment*

Reliable equipment was required for measuring gas purity and for feeding hydrogen to the machine automatically to maintain purity and pressure. Apparatus and instruments for this purpose were available for the most part and there has been no major difficulty to overcome.

6. *Scavenging*

The question of the proper procedures to be used in changing from an air to a hydrogen atmosphere and vice versa, has been given much study and field testing. Provision is included on all machines for scavenging with carbon dioxide if desired, but on the systems with which the authors are associated scavenging is today not employed on condensers.

III. Description of Condenser Installations

In table I are listed all the hydrogen-cooled synchronous condensers installed on the properties of the American Gas and Electric Company systems. Pertinent data covering each machine are included. Since the Fostoria unit is one of the machines more recently installed and because it is representative of the latest developments, this particular installation will be described in detail. A good many of the other units are installed in a more or less similar manner. Where, however, important or interesting features at these other locations exist, they will be described specifically farther on in the text.

A. Fostoria 36,000-Kva Synchronous-Condenser Installation

1. *General*

This 36,000-kva synchronous condenser was installed in December 1936 at the West End station, Fostoria, Ohio, on the system of The Ohio Power Company. Connected through a 40,000-kva four-winding transformer bank to the 132-kv bus, it provides necessary voltage regulation and stability for the 132-kv transmission system in the northwestern portion of Ohio.[6] The unit is quite similar to the 30,000-kva machine at Fort Wayne, Ind., which was installed in 1931. By modifying the design of the frame and accessories for operation at 15 pounds per square inch the increased capacity was obtained. A view of this installation is given in figure 1. The condenser is automatically controlled but supervised by the substation operator in an adjacent control building.

2. *Foundations and Housing for Equipment*

As previously stated, the hydrogen-cooled machine because of its gas-tight construction is naturally weatherproof and therefore adapts itself easily to an

Table I. Hydrogen-Cooled Synchronous Condensers in Service

Listing as of November 30, 1939

			Rating			Type of		
Location	Operating Company	Starting Date for H_2 Operation	Kva	Kv	Speed in RPM	Installation	Water Cooling	Excitation

* Originally used salt water—changed in 1933 to fresh water.

† Rating at 15 pounds per square inch hydrogen pressure. Other machine ratings at 1/2 pound per square inch hydrogen pressure.

** This unit now installed. Operation in hydrogen expected in December 1939.

outdoor installation, thus dispensing with a building for housing it. The Fostoria installation is a typical example of this. The concrete foundations are constructed to provide a suitable pit for housing incoming leads, pumps, piping, and other related equipment. Reference to figure 1 will show that a small entrance structure is located to the left of the condenser. This not only provides an entrance to the pit, but also furnishes space for the hydrogen supply bottles and gas control equipment shown in figure 2. From here steps lead down to the chamber immediately below, in which is located the electronic exciter as shown in figure 3. This chamber is adjacent to the pit immediately beneath the condenser. A compact and economical arrangement thus results. This chamber as well as the pit are both well ventilated to remove the heat losses of the excitation equipment and also to eliminate any possibility of leakage hydrogen being pocketed.

3. *Outer-Shell Construction*

The outer shell is in three sections, a central portion which contains the stator and rotor and supports the bearings, and two end sections which house the coolers. This arrangement is similar to that of the Turner 20,000-kva condenser described in a previous paper.[2] The shell is constructed of boiler plate and is explosion-proof even for operation at 15 pounds per square inch gas pressure. It is made gas-tight by the use of rubber rings installed in grooves at the main joints between shell sections. In addition the usual vellumoid gaskets are installed on these same joints but on the outer portion of the surfaces to assist in sealing the shell and also to prevent deterioration of the rubber rings. Referring to figure 1 there can be seen at the left end of the machine, the housing which is provided for the collector rings and brush rigging. An easily removed cover plate facilitates inspection and adjustment.

Figure 2. Front view of hydrogen-control equipment—Fostoria 36,000-kva synchronous condenser

4. *Cooling System*

Each end of the machine contains two vertical fin-type surface coolers. The cooler heads at the bottom of the machine can be removed and the tubes cleaned without dismantling the machine or removing the gas. By means of integrally mounted rotor fans the hydrogen is caused to circulate inward along the rotor, then outward radially through the stator, and finally through the four coolers and back to the rotor fans. The collector compartment is cooled by means of small radial fans on the shaft which circulate gas from the main shell to this chamber and back again through a connecting pipe at the top of the compartment.

The external water-cooling system consists of a cooling tower to which the water is pumped through the surface coolers by means of two vertical motor-driven pumps mounted on the wall of the pit. The surface coolers are designed to remove full-load heat losses from the machine when 200 gallons of ingoing water per minute at a temperature not exceeding 85 degrees Fahrenheit are used. Each pump has a capacity of 275 gallons per minute permitting normal operation with only one pump. This cooling system also supplies necessary water for the water-cooled bearings, and for the heat exchanger required for cooling the tubes of the electronic exciter.

5. *Bearings and Lubrication System*

The machine uses bearings of standard design with oil rings. Particular attention has been directed to the problem of preventing emission of oil vapor. A copper cooling coil is cast into the bottom half of each bearing. An indicating thermometer bulb and a resistance temperature detector are installed in the bottom half of each bearing. Both bearings are insulated from the frame of the machine, and obviously the water piping must likewise be insulated. Insulated ground connections are brought out from each bearing and normally one of these is connected to ground.

Pipe connections are brought outside the shell for conveniently filling or draining the bearing wells. Magnetic-type gauges located on the side of the condenser shell show the level of oil in each bearing. Connections are brought to each bearing for floating the shaft when starting the machine and two small high-pressure oil pumps are installed for this purpose.

6. *Excitation Equipment*

For simplification purposes separate excitation has been used for hydrogen-ventilated machines. This offers, therefore, an ideal application for an electronic exciter,[7] and such an exciter is installed on the Fostoria machine. A view of the excitation equipment is given in figure 3. This shows seven cabinets, consisting of six tube panels with control, disconnecting and grounding devices, and one regulating and control panel shown on the extreme right.

Figure 3. Front view—electronic-exciter cabinets—Fostoria 36,000-kva synchronous condenser

7. *Collector Compartment, Collector Rings, and Brushes*

To permit inspection and maintenance work on the brushes and collector rings without removing hydrogen from the machine, a separate accessible compartment is included. With the machine stationary, a seal between this compartment and the main shell is closed to prevent loss of gas. This consists of a solid rubber ring normally held a short distance away from a rotating sealing plate on the shaft. To close the seal, a rubber tube arrangement is inflated, thus moving the rubber ring horizontally against the plate above mentioned. This seal is satisfactory for preventing leakage from the main shell for pressures up to 15 pounds per square inch.

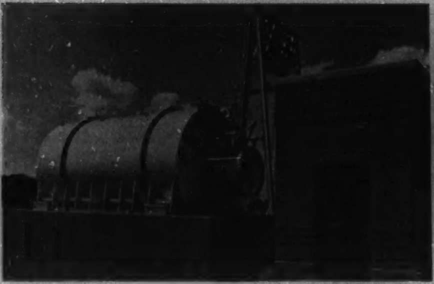

Figure 4. The Torrey 36,000-kva hydrogen-cooled synchronous condenser of The Ohio Power Company at Canton

Figure 5. The 30,000-kva 3,600-rpm hydrogen-cooled synchronous condenser at the New Carlisle station of the Indiana and Michigan Electric Company

Several windows in the collector housing permit inspection of the interior without opening the compartment. The collection of brush dust has always been a problem. Particularly bothersome has been the problem of preventing the carrying of it into the windings of the stator and rotor. A dust trap has therefore been installed on the end of the return pipe connecting from the collector compartment to the main shell, to catch the small amount of solid matter which otherwise would be blown into the main shell.

Grooved bronze-alloy collector rings are employed. Originally, metallized carbon brushes were used of the type common on practically all other similar machines, but because of unsatisfactory operation initially, nonmetallic brushes were tried and are giving excellent performance. The insulation of the brush rigging is greater than is ordinarily used for open-type collector rings in air, a greater leakage surface being required because of the accumulation of brush dust during the periods between inspection and cleaning of the compartment.

8. *Hydrogen Accessories*

Clean dry hydrogen with a purity of 99.6 per cent or more is obtained in steel bottles compressed to a pressure of approximately 2,000 pounds per square inch. By means of a double-diaphragm reducing valve, the pressure is reduced to approximately 25 pounds per square inch for feeding into the machine when operating at 15 pounds per square inch. These bottles and the other accessory equipment are shown in figure 2. The differential draft gauge shows the pressure being developed by the rotor fans, and since change in purity causes a corresponding change in density, and in fan pressure, this instrument gives a reliable and instantaneous indication of gas purity when the machine is running.

With the machine stationary, a continuous sample of gas from the main shell is allowed to pass through the filter, drier, and thermal cell (shown just below the gauge panel), and out through a bubbler bottle to the atmosphere. This entire arrangement has been previously described.[2,3] The range in variation in hydrogen purity that is registered on the indicator is from 90 to 100 per cent. With the machine running the pressure of the rotor fans is utilized to continuously circulate the gas through the analyzing equipment. The purity indicator is located on the condenser panel in the substation control room. Gas pressure in the machine is automatically maintained for either high- or low-pressure operation.

The gas is fed into the machine through a horizontal perforated pipe at the top of the inside of the shell, but the feed pipe actually enters the shell at the bottom, so that all piping, including that for water and oil, is taken care of at the bottom of the unit. This facilitates all connections, and improves the outside appearance of the unit.

9. *Facilities for Inspection and Maintenance*

The provisions supplied for periodic cleaning of the collector compartment and of the surface coolers have been already mentioned. For minor repairs inside the condenser shell, four manholes are included, two at the top and two at the bottom of the shell. There is considerable working space at each end of the machine between the coolers, which permits maintenance work on bearings, piping and other parts, without any disassembly of the shell. A small lifting frame has been developed for bolting to the top of the condenser shell. A portable hoist is easily attached to this frame and facilitates the handling of parts at the collector compartment. In conjunction with the top manholes this frame and hoist can also be used for inspection and replacement of bearings. For complete dismantling of the machine, slots have been provided on the bottom surfaces of the shell sections and by the insertion of rollers in these slots, these heavy pieces can readily be moved.

B. INTERESTING FEATURES OF OTHER SYNCHRONOUS-CONDENSER INSTALLATIONS

The Turner machine, the first unit to be installed, was purchased as a 15,000-kva air-cooled synchronous condenser, but designed for operation in hydrogen at 20,000 kva. Initial tests and early operating experience indicated entirely satisfactory and reliable performance under hydrogen cooling and therefore this machine with almost 11 years of continuous service has operated longer in hydrogen than any other similar machine in this country. The general arrangement is the same as that of the Fostoria unit with the exception that a motor-driven generator is used for excitation purposes. A brief description of this installation was included in a paper presented about ten years ago.[3]

It will be noted, that although the gas-tight shell makes this type of machine suitable for outdoor service, three of the installations are indoor. This was because floor space was available in the power plants at Atlantic City, Scranton, and Kenova at the time it was necessary to install condensers at these locations. Salt water was initially utilized at Atlantic City for the surface coolers, but difficulties with mussels, made it desirable to change over to fresh water. In the case of the Scranton unit, the first application of an electronic exciter for a synchronous condenser was employed.[7]

The Fort Wayne machine operates at 1,200 rpm and is unique in that it was the first synchronous condenser to operate at that speed. This required a new type of rotor design, the same as that later used on the Fostoria and Torrey units. The increased speed permits taking full advantage of the low windage losses of the hydrogen-ventilated machine. As a matter of fact, the design was projected into 1,200 rpm, so as to permit economies possible at that speed, knowing that the increased windage would be substantially nullified by the use of hydrogen. A view of the 1,200 rpm machine at the Torrey station is given in figure 4.

The Benton Harbor unit differs somewhat in design from the Fostoria machine in that the size of the machine was reduced by eliminating entirely the working space at each end on the inside of the unit. Therefore any inspection or maintenance work inside the shell requires the removal of one or both end bells. However, the weight of the latter is small, and therefore a light lifting structure is sufficient to facilitate work on this unit. Of interest is the fact that this machine was made completely automatic in July 1937, indicating the conviction of the authors in the reliability and safety of hydrogen-cooled machinery.

The outstanding feature of the Scarbro condenser is the design of the windings for 24,000-volt operation; the unit is thus the highest-voltage a-c rotating machine operating commercially in the United States. The connection of the condenser to the 44-kv system at this point, is made through a two-winding three-phase transformer. Tests which have been previously covered,[1] indicate that the effect of corona in a hydrogen atmosphere is relatively negligible. It was to obtain experience on this point, that a potential rating higher than that used in general practice, was chosen.

C. New Carlisle 30,000-Kva Synchronous Condenser

The possibility of taking maximum advantage of the low density of hydrogen gas by developing a 3,600-rpm synchronous condenser had occurred to any number of designers and power-system engineers. It had, as a matter of record, been discussed by one of the authors, at length, with engineers of two prominent manufacturers. There seemed to be some doubt, however, as to the point of cross over for most economical design, of the size and cost curves for distributed (two-pole) and salient-pole construction. When, however, the engineers of one of the companies evolved an economical two-pole design in a 30,000-kva size and a need for such a machine arose at the New Carlisle station of the Indiana and Michigan Electric Company, it was decided to make such an installation there.

Table II. Availability and Outage Data, Hydrogen-Cooled Synchronous Condensers

Data as of September 30, 1939

Total	511,752	19,960	491,792	96.10	49,997	452,101	9,654	5,969	98.83
Total—machine years	58.44	2.28	56.16	96.10	5.70	51.63	1.11	0.68	98.83

At the time of writing this paper (October 1939), the installation of this unit is just being completed and it is expected that the machine will be in operation in hydrogen at an early date in December. A view of the unit as installed at New Carlisle is given in figure 5. The general arrangement is similar to that of the Fostoria station, except that the electronic exciter is located in a nearby control building. The machine is suitable for operation at a gas pressure of 15 pounds per square inch and the rating of 30,000 kva is on that basis. The results of factory tests made on this condenser in air and hydrogen are included in section VII.

IV. Operating Experience With Synchronous Condensers

A. General

So many factors influence the operation of synchronous machines in general, and of hydrogen-ventilated machines in particular, that it is extremely difficult to give an absolutely fair picture of operating experience in spite of the fact that over 58 machine years of service are covered by the eight condensers under consideration. In compiling the data, the authors have used as a starting date the first day that each particular unit was operated in hydrogen. Obviously this includes many troubles which occur on most machines only in the first few months or in the first year of operation. On the other hand, to omit any part of the actual operating experience on any of the machines might, by glossing over some pertinent information tend to distort the facts. Although as far as the authors know, no general figures are available regarding the operation of standard air-cooled condensers, they believe the tabulated data which follow, will compare very favorably with similar information on conventional machines running in air.

B. Availability and Outage Time

In table II, there has been condensed information covering the running and outage times of the first eight machines placed in service. The hours given in column *b* include any "forced" outage for inspection or repairs, and cover not only the synchronous condenser but also its accessory equipment such as excitation, oil, water, and gas systems. It does not include switching, main cables, or transformers used for supplying energy to the machine. In the case of two machines, Kenova and Scranton, which were out of service a considerable number of hours because they were not required, there have been obtained outage figures covering any "forced" inspection or maintenance which was carried out while the unit was shut down.

On this basis, availability was determined for each machine and it will be noted that each is above 94 per cent with the exception of the Fostoria unit which, as of the date this was written, had been in service somewhat less than three years. It is fully expected that over a longer period this machine will show results similar to the others.

The total running time in hydrogen for all machines was 51.63 machine years or approximately 88 per cent of the time in service. In case of troubles which necessitated the removal of hydrogen, and which could be repaired immediately, it was usually found desirable, when possible to run the unit in air at reduced capacity. Column *g* includes this running time in air.

There has been included in column *h*, outage time occasioned because of hydrogen accessories or because of constructional details necessary for operation in hydrogen. In this there have been included all inspections of the collector compartment as well as of the main shell. All lost time because of troubles with collector rings and brush rigging has been included, although it is common knowledge that collector-ring and brush trouble is all too frequent on standard synchronous condensers. Any difficulties with oil piping, water connections, or coolers inside the shell have been attributed to hydrogen construction. On this basis there has been determined an availability figure in so far as construction for operation in hydrogen is concerned, and it will be noted that the lowest availability is 97.95 per cent, with the average for all machines being 98.83 per cent.

In order to present a detailed picture of difficulties which have been encountered on these machines, there are given in table III, itemized figures showing the causes for the forced outages on the eight condensers. Further information regarding these troubles is included in the paragraphs which follow, for the principal causes of trouble. More could be given but is being withheld for lack of space. It is interesting to analyze quantitatively the various types of outages which have occurred. Inspections of main shells and collector compartments represent only 8.17 per cent of the total forced outage time. The majority of the hours lost was because of rotor difficulties (38.82 per cent) and troubles with the water cooling systems (20.07 per cent). Of importance also were the following three: excitation equipment (7.83 per cent), collector rings and brushes (7.24 per cent), and vibration (5.46 per cent). Of the forced outage only 29.9 per cent can be attributed to construction for operation in hydrogen. Hydrogen piping and accessories accounted for 0.81 per cent of the forced-outage time.

1. *Rotors and Stators*

On most of the machines no difficulties occurred in connection with the rotating fields or the stator windings. This can be attributed to the exclusion of dust, moisture, and other objectionable components which ordinarily tend to affect adversely the windings and insulation. The condition of the windings on all machines, as revealed by periodic inspections, was found to be excellent, and apparently just as good as when first placed in service. Rotor troubles on three of the machines resulted in long outages in each case, but insulation failure or deterioration did not contribute to these faults. The difficulties were primarily because of new rotor designs for 1,200-rpm operation.

2. *Water Cooling Systems*

Outage time of appreciable amounts occurred on all but one machine in connection with the water cooling systems. The utilization of spray ponds and cooling towers necessarily requires periodic cleaning of the apparatus involved. Experience with these external water cooling equipments has been satisfactory both for summer and winter operation. Some difficulty has occurred because of strong winds blowing away the spray and thus causing excessive water consumption adversely affecting the efficiency of this equipment.

Experience with the internal surface coolers has been likewise very satisfactory. In only one case has leakage occurred on an internal cooler unit and in this instance a slow leak developed at one of the vertical tube connections to its horizontal header plate. A slow but steady accumulation of water in the oil-and-water-leakage detector at the bottom of the machine gave ample warning of this difficulty, which was readily rectified by expanding the bell-shaped end of the tube into the socket of the cooler header plate.

Table III. Segregated Outage Data, Hydrogen-Cooled Synchronous Condensers

Data as of September 30, 1939

			Atlantic City	Benton Harbor	Fort Wayne	Fostoria	Kenova	Scarbro	Scranton	Turner	Total	Per Cent of Forced Outage

* Indicates interior of machine was inspected at time of other major maintenance work.

In another case one of the vent pipes for a cooler failed inside the machine, allowing water to collect in the bottom of the condenser. Although a water-leakage detector was installed, unfortunately a small isolating valve ahead of the detector was closed, and therefore, the operator received no alarm, until the machine tripped from its differential relays. Sufficient water had collected in the bottom of the shell to provide a conducting path between the terminal bushings. A short circuit resulted but no fire ensued since there was no oxygen present to support combustion, and therefore the extent of the damage was minimized.

In two other instances, after about five years' operation, slow leakage developed on the brass water piping to the bearings and it was found at the time of general inspection that dezincification action had eaten pin holes in these connections. All internal water piping on these units has been changed to "red" brass or copper to eliminate any possibility of further difficulty. Similar changes have been or will be made on all other machines.

3. *Outage Due to Operation in Hydrogen*

(*a*). *Bearings and Lubrication System.* Although the bearings are normally inaccessible, their reliability has been found to be such that maintenance on these parts of the machine is relatively small. Temperature indication is obtained by two methods from each bearing for check purposes, and therefore ample warning of overheating is generally obtained to prevent wiping of the babbitt or other damage to the machine. Bearing difficulties have been principally on the two 1,200-rpm machines. Failure of a bearing on one of the lower-speed machines was attributed to shaft currents, which were able to flow because of insufficient clearance between the outboard end of the shaft and the end bell. In another instance, during a general inspection it was found that one of the oil rings was considerably worn on a portion of the inside periphery indicating that it had not been turning for a long period. Nevertheless, no increase in temperature was noted on this bearing, the one remaining ring providing sufficient oil for proper lubrication, as evidenced by the normal condition of the shaft.

One of the problems has been to maintain an adequate flow of water through the bearing cooling coils. Initially these coils were connected in parallel with the main coolers on all machines, and therefore the small pressure drop across the latter determined the effective pressure for circulating water through the bearing coils. In some cases this resulted in slow circulation, clogging of the coils and overheating of the bearings, and it was necessary to discharge the water to the atmosphere to obtain sufficient cooling. Considering the exceptional cooling qualities of hydrogen it seems that a self-cooled bearing might be satisfactorily designed for this service and thus eliminate the somewhat objectionable water-cooled arrangement.

Since the bearings are entirely enclosed inside the shell of the machine, provision must be made for filling the bearings or changing the oil without removing the hydrogen. Oil tanks and pumps are provided on most machines for this purpose, these same pumps being used for obtaining the high oil pressure necessary for lifting the shaft at times of starting the condenser. The only difficulties experienced with this system have been slight leaks which have occurred in the high-pressure piping to the bearings.

Due to the operation in hydrogen, there can be no oxidation of the oil and therefore aside from dissolving a limited amount of hydrogen, the oil remains in such condition that it is unnecessary to periodically renew or recondition it. On most of the machines under discussion, there is still being used the oil which was originally placed in the bearings. Tests were made on samples of oil from the Turner machine as originally installed and after approximately seven years' operation with results as given below:

	Original Oil	Oil After 7 Years' Operation
Specific gravity at 60 deg F	0.889	0.885
Neutralization number (milligrams of potassium hydroxide per gram of oil)	0.07	0.14
Viscosity, Saybolt time, seconds		
at 100 deg F	313	257
at 200 deg F	58	54

There was also a slight change in color. However, for all practical purposes, the oil was the same as it was originally. After almost 11 years this same oil is still in service. This oil is heavier than that used on most machines.

(*b*). *Collector Compartment Seals.* The first five machines installed were equipped with sealing arrangements, which, while satisfactory for the purpose intended, did allow some leakage of gas to the collector compartment. If there is an appreciable leakage of hydrogen at this location, it means that an explosive mixture may be present to a limited extent, and hazard to men working in and near the compartment presented. Only in one case was there sufficient leakage to make this possible and this condition has since been rectified. Later machines are equipped with seals which permit absolutely no leakage. A brief description of the various types is given below together with operating experience.

The Turner machine has a seal, consisting of a carbon ring held continually against a shoulder on the shaft by means of a bellows and six springs equally spaced around the shaft. With this arrangement the collector compartment is sealed from the main shell when the machine is running and therefore two pipe connections are included to permit circulation of the gas between the main shell and this compartment. This arrangement has worked out satisfactorily, although there is a slight leakage through the seal during inspections of the compartment. After approximately seven years' operation the carbon rings were carefully checked and it was found that no appreciable wear had occurred.

The arrangement used on the next three machines installed, consists of a rubber ring normally held a short distance away from a rotating sealing plate bolted to the shaft, thus allowing small fans on the shaft to circulate gas through the compartment. By a system of levers and plates, this ring can be moved horizontally in order to close the gap and thus seal the compartment. Although this has proved to be a good arrangement, there is an uneven pressure applied around the ring, so that there tends to be a slight leakage at some points.

Another scheme similar to that just described was used on the fifth unit but in this case, when the collector compartment end plate is removed, springs which are normally in compression, automatically close the seal. Cork was originally used for the sealing material but because of excessive leakage when the seal was closed, this was changed to composition rubber asbestos. Tests indicate that practically all leakage has been eliminated by this slight alteration.

On later machines, in order to provide an even pressure on the sealing plate, the rubber ring above mentioned is replaced by an annular rubber diaphragm. By pumping air behind the diaphragm, expansion of the rubber is obtained, which closes the seal evenly around the circumference. The experience of the authors, indicates that, while this arrangement is satisfactory, there is a tendency for the rubber to gradually take a permanent set, or pull out of position and therefore, when deflated there may not be sufficient clearance between the rotating sealing plate and the rubber. In one instance, the rubber was worn through, and a replacement was required.

A later development which is being used on the 1,200-rpm machines is an arrangement in which a complete circular rubber tube is used, which, when inflated, moves horizontally a solid rubber ring, similar to that previously described. Experience to date, indicates that this is by far the most efficient sealing arrangement and it has been possible to prevent leakage from the main shell at gas pressures up to 15 pounds per square inch.

Table IV. Gas Consumption and Leakage Data, Hydrogen-Cooled Synchronous Condensers

Data as of September 30, 1939

Location	Kva Rating	Years in Service	Years in Hydrogen	Gas Pressure (Pounds Per Square Inch)	Gas Consumption in Cubic Feet*				
					Total			Average Per Week	
					Normal	Inspection	Total	Normal	Total
Atlantic City	15,000	9.02	8.19	¼ to 1¼	28,613	10,674	39,287	67.1	92.2
Benton Harbor	15,000	8.62	8.29	¼ to 1¼	28,512	10,777	39,289	66.0	91.0
Fort Wayne	30,000	8.67	8.05	¼ to 1¼	66,005	41,985	107,990	157.0	257.0
Kenova	15,000	3.95	3.92	¼t o 1¼	6,164	2,525	8,689	30.2	42.5
Scarbro	15,000	8.58	8.27	¼ to 1¼†	21,450	8,945	30,395	48.0	70.6
Scranton	15,000	6.03	6.02	¼ to 1¼	22,043	2,760	24,803	70.4	79.0
Turner	20,000	10.78	10.69	¼ to 1¼	17,135	10,212	27,347	30.7	49.0
Total		55.65	53.42		180,922	87,878	277,800	68.5	100.0
Fostoria	36,000	2.79	2.17	14 to 16‡	25,431	15,380	40,811	225.0**	360.0
Total		58.44	55.60		215,353	103,258	318,611	74.4	110.0

* Cubic feet of gas consumption calculated at atmospheric pressure and 77 degrees F.

† Operated at 3 to 12 pounds per square inch for approximately three months.

‡ Operated at lower pressures for short periods only.

** Average normal leakage for nine months of 1939 was 12 cubic feet per week.

(*c*) *Hydrogen Equipment and Accessories.* Experience with the miscellaneous equipment necessary for operation in hydrogen has been most satisfactory. The automatic charging equipment for admitting gas to the machine has been entirely reliable and no failure to maintain the desired machine pressure has occurred. A few cases of trouble have been experienced with slow leakage through the solenoid-operated valve when closed and through the pressure-reducing valves located at the hydrogen bottles. It has been found that the hydrogen-purity indicator is not extremely accurate, and depending upon the temperature and humidity of the gas sample, it may indicate as much as two per cent above or below the actual purity. However, in the case of synchronous condensers, since the pressure is maintained above atmospheric, the gas leakage is always outward and therefore it is impossible for the purity to drop. The purity indicator is therefore of real service only at times when the machine is being filled with gas. The main disadvantage of this arrangement is that a considerable period of time elapses before a representative gas sample reaches the analyzing equipment, and therefore there is a time lag of from 15 to 30 minutes, between the purity of the sample and that of the gas in the machine.

With the machine running, a satisfactory and accurate indication of purity is obtained on most units by means of an inclined differential draft gauge, since it responds immediately to changes of purity or density of the gas in the machine. This device has proved to be very reliable for this service. On one of the machines, an arrangement is used consisting of an external fan, which circulates gas from the machine and through an orifice. The differential pressure thus developed is used as a measure of the density, and is therefore calibrated to read hydrogen purity. This arrangement has the advantage that it provides immediate indication of purity changes at all times. It has proved to be satisfactory although extremely accurate results are not obtained.

C. Gas Leakage and Consumption

The problem of hydrogen-gas leakage is one which can easily be over emphasized because of the desire to make the shell as tight as possible regardless of the cost of extra maintenance charges as compared with the low price of the gas which can be saved. Experience indicates that it is a much more difficult matter to prevent hydrogen leakage than air leakage from the same machine. Condensers which tested airtight at 15 pounds per square inch pressure, have shown appreciable hydrogen leakage at pressures below 2 pounds per square inch. It has seemed to the authors from the first, that with a gas pressure only slightly above atmospheric, it should be possible to design joining surfaces, gaskets, and connections and to produce gastight welds so that leakage could be practically eliminated without introducing excessive costs for maintenance and leakage testing. With an appreciable gas loss at low pressure, it means that higher gas pressures cannot be used, if required, without excessive gas consumption, since leakage increases rapidly as the pressure is raised.

With the above in mind, the authors have endeavored to keep to a minimum the gas consumption on these eight machines, without unduly expending funds for material and labor for this specific purpose. There are listed in table IV, gas consumption and leakage data which give a complete picture not only of losses during normal operation, but also for inspection of the collector compartments and the main shells. The total hours in hydrogen include stationary as well as running time. For the seven low-pressure machines, the normal average weekly leakage per unit was 68.5 cubic feet and the total average weekly gas consumption per unit was 100 cubic feet.

In the case of the Fostoria unit, which has been operated at an average pressure of 15 pounds per square inch, the leakage as might be expected, has been quite high. However, in nine months' operation in 1939 the average normal leakage was only 12 cubic feet per week.

While the price of delivered hydrogen gas varies with the location, the authors have found that the average cost, including handling and rental charges on cylinders is approximately two cents per cubic foot for gas at atmospheric pressure and 77 degrees Fahrenheit. On this basis, the average cost of hydrogen per machine year has amounted to $114.

V. Handling of Hydrogen and Its Scavenging Gases

A. Characteristics of Hydrogen-Air Mixtures

It has been reported[8] that 4.1 per cent is the minimum percentage mixture and 74 per cent is the maximum percentage mixture of hydrogen in air, which will burn under the most favorable conditions. This is true for the ranges of temperature and pressure ordinarily encountered but it depends upon the size, material, and shape of the container. In the case of mixtures of low-hydrogen content complete combustion under the best possible conditions will not occur until a mixture of approximately 10 per cent is reached. In igniting various mixtures of hydrogen in air, tests indicate that no appreciable or rapid increase in pressure is obtained in a sealed chamber for mixtures below 10 per cent or above 70 per cent. These values are therefore generally used as the lower and upper explosive limits for hydrogen-air mixtures.

The above figures are based on uniformly diffused mixtures of hydrogen in air and do not take into account the cooling effect of surrounding objects, such as stator, rotor, cooling coils, etc., as they exist inside a synchronous machine. Incomplete diffusion and absorption of heat by adjacent material considerably decrease the range in which the mixture is inflammable. However, it is absolutely certain that a thoroughly diffused hydrogen-air mixture at temperatures and pressures ordinarily encountered, will not be inflammable below 4.1 per cent or above 74 per cent with the practical upper and lower limits closer together than this. This lower limit is the one which has been used in maintenance work on the authors' systems as a basis for determining when it is safe to enter the machine or start it in air after removing the hydrogen. For normal operation of the condenser in hydrogen a lower limit of 90 per cent hydrogen in air is used thus allowing an ample safety margin.

B. Scavenging

When the first machine was placed in service in 1928, the manufacturer recommended the use of an inert gas such as nitrogen or carbon dioxide as an intermediate medium for scavenging purposes when filling the machine with hydrogen, or when removing the gas from the machine. These procedures were intended to eliminate the possibility of ever having explosive mixtures of hydrogen and air inside the condenser. However, when the second machine went into operation in 1930, it was felt that the use of carbon dioxide was unnecessary as long as reasonable precautions were taken in the handling of air and hydrogen mixtures. With the advice of the manufacturer there was adopted at that time the procedure of replacing the air by blowing in the hydrogen gas without utilizing any scavenging operation, and vice versa for removing the gas. There is only a very short period of time during which there is a possibility of having such an explosive mixture, and at that time the gases are only partially diffused into each other With the machine stationary and deenergized there is only a very remote possibility of igniting the mixture. Furthermore, if an explosion should take place, the shell is able to withstand any pressures which might be developed, and little if any damage would result internally. This practice of employing no intermediate scavenging medium for the gassing and degassing operations is now consistently followed on all synchronous-condenser installations of the authors' systems. However, in the case of turbogenerators carbon dioxide is used as a precautionary measure because the machine is generally being rotated by the turning gear during the period when it is desired to change from air to hydrogen or vice versa. Furthermore, in an emergency it is possible to change from hydrogen to carbon dioxide to air without disconnecting the unit from the line by decreasing the load to the air-cooled rating. Outage time on a large turbogenerator is obviously a much more expensive proposition than it is on a synchronous condenser.

C. Procedures Used for Introducing Hydrogen Into Condensers

On all the machines, the hydrogen is admitted inside the unit at the top through a perforated pipe running horizontally the entire length of the machine. Initially, gas is admitted slowly, thus permitting the hydrogen to flow evenly, forming a layer which gradually moves downward, forcing out the air below. The speed is gradually increased until an amount somewhat less than the machine gas volume has been used. The rate of feeding is then decreased to avoid unnecessary waste of time and gas in blowing out the remaining air. Very little mixing of the gas and air is thus obtained and as a result, the desired purity of above 90 per cent is obtained in about three hours depending upon the gas volume of the condenser. This is accomplished by the use of approximately 50 per cent more gas than the machine will hold. In other words $1^1/_2$ volumes of gas are required to obtain a purity of approximately 95 per cent at the bottom of the condenser. After diffusion with the pure gas at the top of the unit, the gas purity throughout the machine becomes approximately 97%.

D. Procedures Used for Removing Hydrogen From Condensers

None of the first eight condensers has been equipped with similar facilities for spreading out the air (or carbon dioxide) when it is blown in at the bottom of the machine. In fact, on the earlier machines it was necessary to introduce the air at one point only, thus producing a great amount of turbulence and mixing of the gases. On the later machines additional openings have been provided at several points so that air may be introduced more uniformly and thus replace the gas more quickly and efficiently. In the case of turbogenerators which the authors have installed, a V-shaped inverted and perforated trough has been provided at the bottom of the units to facilitate the proper entrance of scavenging gas or air.

After blowing in air for several hours, samples are taken from the top of the machine and from the collector compartment, and when these samples indicate the presence of three per cent or less of hydrogen this is taken as an indication that it is absolutely safe to start or enter the machine. For making these purity determinations, there is being used a portable sampling device and combustible-gas indicator, which is reasonably accurate for the lower percentage of hydrogen-in-air mixtures, that is from 0 to 20 per cent. This device has proved to be very reliable under all operating conditions. It is also a very helpful accessory for locating gas leaks and for checking the percentage of hydrogen present at various locations in and around the machine.

E. Characteristics of Hydrogen-Air-Nitrogen and Hydrogen-Air-Carbon-Dioxide Mixtures

The inert gases ordinarily used for the scavenging of hydrogen-cooled machines are nitrogen and carbon dioxide. It is necessary to know definitely the inflammable limits of mixtures of these gases with air and hydrogen in order to determine when the proper amount of either gas has been used in changing from air to hydrogen and vice versa. If these scavenging gases are used in insufficient amounts or in a haphazard manner, the effect is worse than if no inert gas were employed, because there is not only the possibility that an explosive mixture may exist at some location in the machine, but also a false sense of security may be given to the operator.

The inflammability limits of hydrogen-air-nitrogen and hydrogen-air carbon-dioxide mixtures have been reported elsewhere.[8,9] The amount of gas required for scavenging purposes has likewise been discussed previously.[9] On the basis of perfect diffusion and theoretically, 1.4 machine volumes of nitrogen or 1.3 machine volumes of carbon dioxide are required in changing from air to hydrogen in order to eliminate the possibility of having an inflammable mixture of gases present in the machine at any time. Similarly, in changing from hydrogen to air, 3.2 machine volumes of nitrogen or carbon dioxide are required.

These theoretical figures are reduced by the fact that the cooling effect of the parts inside the machine raise and lower respectively the lower and upper inflammable limits. Furthermore, the amount of gas actually required is considerably less than that calculated, especially with the use of carbon dioxide, since, if the gases are handled smoothly, properly, and with reasonable speed there is very little mixing or diffusion.

As a result of these factors, it has been found in the case of the Logan and Windsor units, that for the filling operation, after approximately 0.8 machine volumes of carbon dioxide have been introduced, a 75 per cent concentration of carbon dioxide is obtained at the top of the machine, with approximately 100 per cent carbon dioxide at the bottom, which means an average of about 90 per cent. In the case of removing hydrogen, a concentration of 95 per cent carbon dioxide is obtained at the top of the unit, after approximately 1.2 machine volumes of scavenging gas have been used. Everything considered, it is believed best to obtain as a minimum a 75 per cent concentration of carbon dioxide at the top of the unit when changing from air to hydrogen, and a 90 per cent concentration when changing from hydrogen to air.

F. Nitrogen Versus Carbon Dioxide as a Scavenging Medium

While either nitrogen or carbon dioxide can be satisfactorily employed for the scavenging of hydrogen-ventilated machines, the latter is generally used for the following reasons:

(*a*). The inflammability range for hydrogen-air-carbon-dioxide mixtures is less than for hydrogen-air-nitrogen mixtures and therefore less gas is required;

(*b*). The cost per cubic foot of carbon dioxide is approximately one-third that for dry nitrogen;

(*c*). Liquid carbon dioxide is more widely available throughout the country than is compressed nitrogen;

(*d*). Carbon dioxide is approximately 50 per cent heavier than air and thus better adapted for efficient and rapid removal of air or hydrogen without excessive mixing of gases. Nitrogen is approximately the same weight as air.

The only disadvantages which are offered by the utilization of carbon dioxide are as follows:

(*a*). Nitrogen could be more readily handled since, in the case of carbon dioxide it has been found desirable to apply heat to the bottles and connections to prevent freezing of the liquid gas, unless the operation were to be carried on at an excessively low or high speed. However, heating facilities can economically be provided and introduce very little complication into the scavenging procedures. Several methods for introducing carbon dioxide without heating have been developed and undoubtedly these will further simplify the scavenging problem.

(*b*). For a rapid change from hydrogen to air without shutting down of the unit, nitrogen would be preferable since obviously the machine will run just as well in nitrogen as in air, and therefore blowing in of air would be eliminated. However, such emergency changes of gas with the machine in service, would seldom, if ever, be required, and even then, it is possible to continue operation while changing to carbon dioxide and then to air.

G. Handling of Carbon Dioxide

Pure dry liquid carbon dioxide is obtained in cylinders containing 50 pounds which, when converted to gas at atmospheric pressure and at 70 degrees Fahrenheit produce approximately 435 cubic feet. During this change from the liquid to the gaseous state, it has been preferable to apply heat to the bottles. There has been provided for this purpose, a steam-heated hot-water bath in which the cylinders are placed in pairs. Gas is generated at a pressure of approximately 900 pounds per square inch. The cold mixture of gaseous and slightly liquid carbon dioxide is passed through a heating coil in another small hot-water bath, and thence through a reducing valve, from which gas at a pressure of approximately 20 pounds per square inch is obtained. It is then passed into the bottom of the generator, through the perforated trough previously mentioned, and in this manner the gas is uniformly distributed along the length of the machine. In the case of changing from air to carbon dioxide, the air above being approximately 35 per cent lighter than the carbon dioxide, is displaced and allowed to escape to the atmosphere. Test samples of gas are taken from the top of the machine during the latter part of the scavenging process to check that sufficient carbon dioxide has been used. The carbon dioxide is then replaced by hydrogen in the same manner as described in paragraph *C* of this section.

For changing from hydrogen to air, carbon dioxide is admitted at the bottom as described above. Since hydrogen weighs only about five per cent as much as carbon dioxide, there will be practically no mixing of the gases. When tests indicate that only ten per cent of hydrogen remains at the top of the machine, the mixture of carbon dioxide and hydrogen is then removed by blowing in dry compressed air through the perforated pipe at the top of the generator. When test samples taken at the bottom indicate that the carbon dioxide has been practically all removed, and that there is less than three per cent of hydrogen left in the gas mixture, the machine is ready for operation in air, or for inspection and maintenance work if necessary at this time.

VI. Maintenance Routine and Inspections

A. Maintenance Routine

After one year's operation the Turner synchronous condenser was opened for inspection and the interior found to be in such excellent condition that it was decided to allow the machine to operate five years before the next inspection. This original more or less at random chosen, but highly desirable nevertheless, inspection schedule has become established as a permanent maintenance routine. In other words, one year after a new machine is cut into service the gas is removed and an inspection made through the manholes to locate any difficulties which are apt to develop in the initial year of operation. Following this first inspection, unless there is some other evidence of trouble inside the machine, a period of approximately five years is allowed to elapse before making the second inspection. At this time the machine is partly dismantled by removing the end bells, the bearings are inspected, and a careful examination made of the rotor, stator, connections, piping, etc. These inspections require approximately five days.

The original recommendation for inspection of collector compartments was twice a year. In some cases the amount of dust collected in six months seemed to make it unnecessary to clean the compartment oftener than once a year, and in several cases this practice was adopted. However, in the past few years there have been experienced several instances of collector ring and brush trouble which occurred quite unexpectedly. A suggestion was therefore made to the operating companies that the collector compartments be opened not less than twice a year, and preferably three times a year. The time required for this work in general is approximately four hours. Periodic cleaning of the exciters is taken care of at the same time.

Cleaning of the surface coolers is necessary every two or three years depending upon local conditions and primarily upon the characteristics of the cooling water. In several cases water-softening equipment has been installed to prevent formation of scale in the coolers and piping. In general the time required for this cleaning varies from 24 to 72 hours. The spray ponds or cooling towers require cleaning at least once a year.

B. General Inspections

General inspections which have been made on these machines all revealed items of interest. Below are included brief descriptions of a few of these inspections together with views of disassembled machines which will thus present a more complete picture of the maintenance and inspection problem on hydrogen-cooled equipment.

1. *Inspection of Turner Condenser*

An inspection of this machine was made in September 1935, after practically continuous operation of five years and seven months subsequent to the first inspection (which occurred 13 months after being placed in service). The condition of the various parts of the machine as found is given below.

The stator and field windings were found to be in excellent condition. It was noted that a slight amount of carbon dust had been carried in from the collector compartment. Figure 6, taken before the interior parts were touched, shows clearly the clean and excellent condition of the coils and other parts.

There were no apparent leaks in the cooler tubes and connections, or in the brass water piping to the bearings. However, upon test with water pressure, leakage was indicated on the piping to the bearings and there were found several pin holes which had been caused by dezincification.

Lubricating oil originally placed in this machine was never changed. Samples of the oil in this machine were taken and the old oil pumped back into the bearings for continued use. Slight oil leaks were found at the two ends of the machine amounting altogether to about two quarts. Both bearings were inspected and the shaft and bearing surfaces found to be in excellent condition. The oil rings showed no signs of wear.

The carbon ring used for the collector compartment seal, and which is continuously held pressed against the shoulder of the shaft with the machine running or stationary, was found to be polished smooth but there was no appreciable wear. The shaft shoulder had a fine smooth surface. Upon check it was found that the sealing arrangement was working more satisfactorily than originally. The bronze-alloy collector rings were polished smooth with no ridges and no wear. The 24 brushes originally installed on the machine were still in service, the average wear being $^{1}/_{2}$ inch per brush or approximately $^{1}/_{16}$ inch per year. The vent pipe leading back to the main shell was found to contain an appreciable amount of carbon dust, but only a negligible amount of dust was located inside the main shell. All of the various devices and instruments for the handling of the hydrogen gas were found to be in good operating condition.

2. *Scarbro Condenser*

After $4^{3}/_{4}$ years' operation, the Scarbro 24,000-volt machine was shut down because of vibration difficulties and because the five-year general inspection was about due. The condition of the various parts of the machine as found was similar to that of the Turner unit, with the following exceptions.

Figure 6. A view of the windings and interior after $6^{3}/_{4}$ years' service on the Turner 20,000-kva synchronous condenser of the Appalachian Electric Power Company

It was found that the wedges for holding the rotor pole pieces in place were loosened and it was assumed that this accounted for the vibration which had developed over a period of years. All of these wedges were driven in at each end of the machine and trial runs at light load indicated that practically all the vibration had been eliminated.

One of the bearing oil rings was worn down approximately $^{3}/_{16}$ inch for a short distance on the inside periphery of the ring. Apparently this ring had not been turning for a long period. Most of the brass dust from this worn ring had collected in the bottom half of the bearing but some had been carried throughout the lubricating system and it was necessary to thoroughly flush and clean all connections. New oil but of original specification was used for replacement. There was a considerable amount of oil collected at one end of the machine which had apparently leaked from the high-pressure pipe connection. One of the collector rings was in satisfactory condition but a groove $^{1}/_{2}$ inch wide and approximately $^{1}/_{64}$ inch deep had been worn in the center of the other ring. The 20 brushes originally installed were still in service. The average wear was $^{19}/_{32}$ inch per brush or approximately $^{1}/_{8}$ inch per year.

After the tightening of the pole pieces on the rotor in 1935, it was thought that the vibration difficulties had been eliminated. However, in September 1936 vibration was experienced intermittently regardless of load or other variable factors. The machine was opened up at this time for thorough inspection and testing to determine the cause of this unbalancing. It was found that one of the field coils was partially short-circuited and a new coil was installed. Figure 7 shows the rotor removed from the machine and indicates clearly the construction of the rotor and other parts of the machine. After reassembly and test, it was found that vibration still occurred under certain conditions and it was finally decided that the vertical members supporting the bearings were not sufficiently rigid. Additional bracing was installed. Since that time no further difficulty has been experienced with vibration on this unit.

3. *Fort Wayne Condenser*

In 1936 trouble developed in the collector compartment resulting in a short cir-

Figure 7. A view of rotor and stator after $5^1/_2$ years' service on the Scarbro 15,000-kva 24-kv synchronous condenser of the Appalachian Electric Power Company

cuit between rings which froze all brushes to their holders on one of the brush rigging segments, and badly burned one of the rings. This failure occurred primarily because there was insufficient insulation on the brush rigging and secondly because of the large amount of carbon dust collected on these insulating surfaces although this compartment had been cleaned several months previously. At this time the hydrogen was removed by the usual method of blowing air into the bottom of the machine. After it was thought that all of the gas had been removed from the machine, an attempt was made to start for the purpose of truing the collector rings. At this instant a minor explosion occurred. The spark necessary for igniting the explosive mixture was obtained from the amortisseur winding during the starting operation. Although inspection indicated no severe damage had occurred, it was thought advisable to disassemble the machine for a thorough inspection, especially since up to this time the machine had been in service approximately $5^1/_2$ years. The condition of the various parts of the machine as found is given below.

The stator and rotor windings were found to be in excellent condition and to have been unaffected whatsoever by the explosion. Many of the baffle plates around the coolers (as shown in figure 8) were bent or torn loose. It was necessary to straighten or replace this material. Fiber portions of the deflectors at one of the bearings were completely blown off. The only indication of heat was the slight charring of the felt padding used for the metal baffling plates. Since the collector compartment end plate was removed at the time, the force of the explosion was directed against the seal and out through this compartment to the atmosphere. The seal was damaged somewhat but was reinstalled and was satisfactory for continued service. There were no signs of leakage in the coolers, the water piping, or the oil piping. Both bearings were found to be in satisfactory condition.

Both collector rings were turned down, damaged brush holders replaced, and most of the 14 brushes replaced. The average wear over the $5^1/_2$ year operating period was $^{15}/_{32}$ inch or approximately $^3/_{32}$ inch per year. The design of the brush rigging insulation was modified to obtain an increase in the length of the insulating surfaces. During this complete disassembly, thorough inspection, and reassembly, the machine was out of service for a period of 14 days. It was operated in air several weeks before again being filled with hydrogen.

VII. Synchronous-Condenser Losses and Test Data

A. Operation in Air and Hydrogen

Test data covering the first machine installed in 1928 are presented for the purpose of comparing operation in air and hydrogen. Factory test data are also included for the 3,600-rpm machine about to be placed in service at New Carlisle, Ind.

1. *Temperature Runs and No-Load Tests on Turner Condenser*

The Turner machine is rated 15,000 kva as an air-cooled condenser, and 20,000 kva as a hydrogen-cooled machine operating at gas pressures slightly above atmospheric. When the machine was placed in operation in December 1928, temperature runs and no-load tests were made in air and hydrogen at the Turner station. The results of the temperature runs are given in table V. It will be noted that the temperature rises for rated loads in air and hydrogen (at low pressure) were of the same order, thus demonstrating that the use of hydrogen increased the machine capacity by approximately 5,000 kva. A better comparison is obtained from runs numbers 2 and 4, since the maximum possible load was carried in each case without exceeding the guaranteed temperature rises. The increase in capacity from 19,000 to 24,000 kva for this particular machine, indicates that in general an additional capacity of 25 per cent above the air-cooled rating can be obtained by the use of an atmosphere of low-pressure hydrogen. The results of test number 5 are analyzed in section VIII-*B*.

The measured no-load loss in air, excluding excitation losses, amounted to 172.5 kw. This comprises a core loss of 70.5 kw, a friction loss of 12 kw, and a windage loss of 90 kw. For operation in hydrogen the similar no-load loss was 90 kw with the windage amounting to 7.5 kw. At 15 pounds per square inch operation, the windage loss is approximately doubled. The effect upon losses of operation in air and in hydrogen at low and high pressures is shown by the curves in figure 9, which include the total losses of the Turner machine at various loads. Making a comparison at 20,000-kva load, the total losses in air are 1.98 per cent of

Figure 8. A view of surface coolers taken during 1936 general inspection—Fort Wayne 30,000-kva synchronous condenser of the Indiana and Michigan Electric Company

the machine rating and in the case of hydrogen 1.53 per cent. For 15 pounds operation, the total loss is 1.57 per cent of the machine rating. For operation in hydrogen the windage loss is such a small part of the total that only a slight increase in total losses results when changing from low pressure to high pressure.

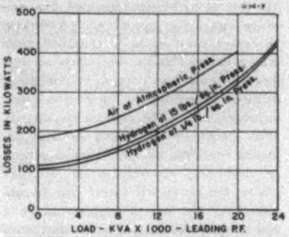

Figure 9. Curves of total losses in air and hydrogen (at normal voltage and frequency, and at leading power factor); 20,000-kva 11.5-kv synchronous condenser, Turner station of the Appalachian Electric Power Company

2. *Temperature Runs on New Carlisle Condenser*

The New Carlisle machine is rated 25,000 kva as a hydrogen-cooled machine when operating at gas pressures slightly above atmospheric, and 30,000 kva when operating at a pressure of 15 pounds per square inch. Temperature runs in air and hydrogen were made on the factory test floor at East Pittsburgh, as given in table VI. It will be noted that in test number 1, a load of 25,000 kva was carried in air, with temperature rises well within safe limits. In test number 2 a load of 30,000 kva was maintained in a hydrogen atmosphere of two pounds per square inch and the temperature rises were of the same order as in test number 1. For this reason the authors consider this unit to have an actual safe rating of 30,000 kva in hydrogen at low pressure and therefore the loss curve in figure 10 was computed on that basis. The unusually small temperature rises of the field can be attributed to the use of a new field coil and slot design which allows the conductors to be cooled directly by the ventilating medium as is the case in salient-pole construction.

B. Losses Versus Speed

In figure 10 there have been plotted curves showing the percentage losses from no load to full load leading power factor for typical machines now in service. The percentage losses of the 15,000-kva 900-rpm units are somewhat less than those of the original 20,000-kva 900-rpm unit at Turner which resulted undoubtedly from improvements in design. The 1,200-rpm 30,000-kva unit shows still further progress in the matter of reducing losses although increase in size was a contributing factor. The 36,000-kva machine covered by curve 4 is practically a duplicate of the 30,000-kva machine of curve 5, and therefore the effect upon percentage losses of increasing the gas pressure to 15 pounds per square inch is clearly shown.

In general, it is found that friction and windage losses increase slightly at the higher speeds and that the stator loss decreases. Field losses and open-circuit core losses remain approximately constant and load loss decreases with increased speed for the salient-pole units. However, in the case of the 3,600-rpm unit, the adaptation of an existing turbogenerator design for condenser service, with the necessary provision of features for decreasing the high starting currents resulted in a percentage load loss, considerably greater than obtained on the lower-speed salient-pole machines. It is hoped on future designs at this speed and with larger capacity units, that losses occasioned by load and other factors can be considerably decreased with the result that the 3,600-rpm machine will have percentage total losses as low or lower than those of the slower-speed units.

VIII. Operation at Higher Gas Pressures

A. General

The maximum benefits from hydrogen cooling are not obtained until gas pressures considerably higher than atmospheric, and of more of the order of 15 pounds per square inch above atmospheric, or even higher, are employed. Increasing the hydrogen pressure enables the gas more efficiently to remove the heat from the windings. The rate of surface heat dissipation by forced convection increases almost directly with the absolute gas pressure, thus more readily transferring the heat to the coolers. As a result, for the same cooling-water temperature, lower field and stator temperatures are obtained as the gas pressure is increased. This is true up to some limit not as yet definitely determined. At the time of the purchase of the Turner machine, the advantage of high-pressure operation was fully realized, and test runs were made at 15 pounds per square inch. However, the gas leakage at this pressure was excessive, primarily because the condenser was not particularly designed for

Tests made at Turner station in December 1928.

operation at pressures above two pounds per square inch. In planning and building the Fostoria unit, high-pressure operation was definitely taken into consideration, and its rating of 36,000 kva is based upon a gas pressure of 15 pounds per square inch. Experience and special tests on this machine and others at high pressure are given below.

B. TESTS ON TURNER 20,000-KVA SYNCHRONOUS CONDENSER

The special tests made on the 20,000-kva synchronous condenser at the Turner station were described in section VII and the results of temperature runs at 0.3 and 15 pounds per square inch gas pressure are included in table V.

The effect of high-pressure operation can be readily seen by comparing the results of tests numbers 4 and 5 since the load carried in each case was approximately the same. The temperature rise of the stator is 11 degrees less, and that of the rotor 19$^1/_2$ degrees less than at the lower pressure. The bearing temperature rises were also several degrees less. This indicates the ability of the gas at higher pressures more effectively to carry away the heat from the bearings and windings and transfer it to the cooling water. Note that the gas temperature drop through the coolers was 18.5 degrees for operation at a pressure of 0.3 pound per square inch and only 12.5 degrees at 15 pounds per square inch or a reduction of 33 per cent.

It will be noted that the machine carried 25,000 kva at 15 pounds per square inch pressure or 25 per cent above its rating at 0.3 pound per square inch gas pressure with the same stator temperature rise and with a somewhat higher temperature rise of the rotor. It is evident that approximately 24,000 kva could have been carried at the higher pressure with a field temperature rise corresponding to that of test number 3 or 20,000 kva at low gas pressure, or in other words a 20 per cent increase.

After approximately seven years' operation, gas-leakage tests were made on the Turner machine at pressures up to 15 pounds per square inch. The results obtained were as follows:

Average Pressure (Pounds Per Square Inch)	Leakage (Cubic Feet) Per Hour	Per Week
14.6	110	18,480
9.5	32	5,376
4.7	6	1,008
0.5 (average over 11 years)	0.2	31

These tests indicated that the excessive gas leakage at the higher pressures was occurring primarily through welded joints as well as through the main shell joints of which there are four on this machine. It indicated, in general, that a given machine must have been designed and tested for high gas-pressure operation in order that satisfactory results may be obtained.

C. OPERATION OF SCARBRO CONDENSER AT HIGHER GAS PRESSURES

The design of the 15,000-kva synchronous condenser at Scarbro was based on operation at gas pressures not exceeding two pounds per square inch. For a period of two months during the latter part of 1938, it became desirable to be able to carry 20,000 kva on this machine in order to maintain voltage for carrying additional load in an adjacent area. This increased capacity was required for only a few hours each day. The pressure was boosted to a maximum of 12 pounds per square inch and maintained through a range of 5 to 12 pounds per square inch for the entire period with satisfactory results.

The temperature of the gas from the coolers was not allowed to exceed 40 degrees centigrade and the field temperature was not allowed to exceed 115 degrees centigrade. (The upper limit being 120 degrees.) Although on several occasions temperatures were reached very close to these limits, it was possible to carry the increased loads required for the necessary periods and maintain properly the system voltage. The chief difficulty was to obtain adequate cooling with the increased losses involved; although the machine rating is based on ingoing cooling water of a temperature not exceeding 85 degrees Fahrenheit, this entering water actually reached a maximum temperature of 93 degrees Fahrenheit.

The gas leakage on this machine at an average pressure of $^1/_2$ pound per square inch has been averaging approximately 7.0 cubic feet per day. During the run at higher pressures, referred to above, this gas leakage was approximately 25 cubic feet per day at 5 pounds per square inch and approximately 100 cubic feet per day at 12 pounds per square inch. It is thus seen that increased load can readily be carried in some cases on these low-pressure machines by increasing the gas pressure, provided the exciters, switching equipment, etc., have the necessary additional capacity.

D. TESTS ON FOSTORIA 36,000-KVA SYNCHRONOUS CONDENSER

In September 1937, five temperature runs were made on the Fostoria synchronous condenser at the following average hydrogen gas pressures: 1, 5, 10, 15, and 20 pounds per square inch. The purpose was to determine the maximum loading which could be carried at each pressure without exceeding the guaranteed field temperature rise of 80 degrees centigrade. The results of these tests are presented in table VII which includes kilovolt-ampere load carried, field current and voltage, temperature rises of various parts, and other pertinent data. Several uncontrollable factors made it impossible to secure results such as could ordinarily be obtained in similar tests at the factory. Most important of these was the fact that an overvoltage of from five to eight per cent was applied to the terminals of the machine which increased the core loss above that which would have occurred at normal voltage, and at the same time made necessary an increase in the field current to obtain the same reactive kilovolt-ampere load. The kilovolt-ampere loads, which would have been obtained at rated voltage corresponding to the field currents actually applied, were calculated and are also included in the table. The total losses under these assumed loadings would have been approximately the same as those obtained during the corresponding temperature runs and these values give a true picture of machine capacity. It is seen that for each five pounds per square inch increase in gas pressure, it is possible to obtain approximately 2,000 kva additional capacity. Obviously the limiting feature is the ability of the coolers to remove the increased heat losses occasioned by the additional loading. The Fostoria unit is not designed for continuous operation above 36,000-kva load, but for short periods will safely carry a considerable amount above its normal rating.

Figure 11. View of 50,000-kva 3,600-rpm hydrogen-cooled turbogenerator from collector end—Logan plant of the Appalachian Electric Power Company

The effect of forced heat convection at higher pressures is indicated by the fact that the gas-temperature drop through the coolers steadily drops off with increase in gas pressure as well as increase in losses so that at 15 pounds per square inch this drop is 10.5 degrees compared to 16 degrees at 1 pound per square inch, although the losses have increased about 33 per cent. These corresponding temperature data at 20 pounds per square inch are not representative, because of the field-temperature rise of 87.5 degrees, which occurred because of changing system conditions. It will be seen that the temperature rises of the bearings were consistently lower with increase in pressure, when the temperature rise of the rotor is taken into consideration. The percentage increases in temperature rise for the cooling water, agree very closely with the percentage increases of calculated losses, as is to be expected since the quantity of cooling water circulated was approximately the same for all tests.

E. OPERATING RESULTS WITH FOSTORIA CONDENSER AT A GAS PRESSURE OF 15 POUNDS PER SQUARE INCH

As mentioned in section III, the Fostoria unit is the first synchronous condenser designed for operation at 15 pounds per square inch pressure. The changes in construction of the shell, joints, and other parts, to make it explosionproof and gastight for the higher operating pressure have already been mentioned. This operating experience is included in section IV, where it is stated that the relatively low availability factor was occasioned by a long outage because of rotor trouble, and by the fact that this unit has been in service for slightly less than three years. During the period from January 1, 1938, to September 30, 1939, this machine was out of service 379 hours, making its availability factor for this period 97.53 per cent which compares very favorably with the results obtained for the other units, which are operated at low gas pressure.

There has been no difficulty in carrying loads of 36,000 kva at all times through the year, and swings as high as 70,000 kva have apparently caused no difficulties. The loading of this machine is controlled primarily by the requirements of the 132-kv system, the voltage of which at this point is maintained largely by means of this machine with its electronic regulator and exciter. In addition a field-temperature controller is provided to step back partially the field current in case the field temperature reaches approximately 100 degrees centigrade. This prevents overloading of the unit which would otherwise make necessary a complete shutdown to allow removal of excess heat losses.

The miscellaneous equipment necessary for maintaining the gas pressure at 15 pounds per square inch has worked out satisfactorily. The fine experience with the collector compartment seal has already been mentioned. Gas leakage data is included in section IV. However, it may be well to point out that the leakage figures given, include the excessive loss of gas which occurred during the first few months of operation. The normal average leakage in 1938 amounted to 185 cubic feet per week and the total average gas consumption to 272 cubic feet per week. Experience in nine months of 1939 has resulted in a normal average leakage of only 12 cubic feet per week, so that apparently less gas will be used on this high-pressure unit than on any of the machines running at low pressure.

F. Tests on New Carlisle 30,000-Kva Synchronous Condenser

The results of temperature runs made on this 30,000-kva 3,600-rpm machine at 2 and 15 pounds per square inch gas pressure are included in table VI. The increased cooling effect at the higher pressure is clearly shown and the possibility of obtaining a capacity of approximately 36,000 kva at 15 pounds per square inch is definitely indicated.

IX. Hydrogen-Cooled Turbogenerators

A. The Logan 50,000-Kva Turbogenerator

1. *General*

Early in 1935 studies indicated the desirability of installing at Logan, W. Va., a 40,000-kw 3,600-rpm high-pressure superposition turbine, in order most economically to develop and increase the capacity of the existing power plant at this location. At that time the cooling of the rotor for a generator of this size and speed could be accomplished only by using hydrogen ventilation. Following the extensive and successful experience with the seven hydrogen-cooled synchronous condensers then in service, the authors unhesitatingly accepted hydrogen cooling for this new generating unit. This machine being the first of this type to be placed on order, initiated a new era of hydrogen-ventilated turbogenerators as indicated by the fact that a great many such units aggregating several million kilowatts are now in service or under construction. The only possible doubtful point, as far as operation in hydrogen was concerned, was the problem of shaft sealing, but extensive tests[11] and factory operating experience with the oil seal at Schenectady over a period of years, provided a basis for anticipating satisfactory performance from this sealing arrangement in power-station service.

2. *General Description of Installation*

The Logan unit has a normal rating of 50,000 kva at 0.8 power factor when operating in hydrogen at a pressure of approximately one-half pound per square inch and with the temperature of raw cooling water for the pad liquid heat exchangers, not exceeding 85 degrees Fahrenheit. A view of the complete turbine generator with direct-connected exciters is given in figure 11. The control panels for the turbine, generator, shaft-sealing system, and hydrogen equipment are located adjacent to the machine as shown, in the main turbine room with necessary pumps, tanks, heat exchangers, etc., placed below the unit on two operating floor levels. The main oil tank is directly under the generator, with the twin oil pumps driven by vertical shafts from the reduction gearing above. In conformance with the latest fire-prevention design for turbine lubricating systems, all oil feed pipes are enclosed in the return piping from the various parts of the unit.

A two-piece explosionproof shell split horizontally provides the outer covering for the generator using a construction somewhat like that of the previous synchronous condensers. The bearings are supported by the end bells, which are also split horizontally to facilitate assembly and inspection of the bearings and interior. Metal-to-metal joints are used on the outer shell with grooves filled with a plastic sealing compound to prevent gas leakage. Instead of the conventional type of internal surface coolers, numerous hollow Monel-metal cooling pads are installed between the groups of stator laminations and distilled water is circulated through the pads to absorb heat from the core by direct contact as previously described.[3] Finned pads are placed in the central portion of the core, which in addition to cooling the stator iron, also remove heat from the hydrogen, as the gas is circulated through them by the action of the rotor fans. Thus, the cooling of the rotor and of the stator end turns is effected by means of the gas. The pad liquid is cooled by circulation through one or two heat exchangers, as determined by the temperature of the raw cooling water.

3. *Shaft-Sealing System—Description*

The problem of shell construction to eliminate gas leakage is similar to that which obtains for synchronous condensers, with the important exception that a shaft seal of the oil-film type is provided in each generator bearing to prevent escape of hydrogen where the shaft passes through the end shields. This system has been described previously in detail.[3,11,12] The Logan installation is designed so that the generator may be operated at gas pressures as high as 15 pounds per square inch. Although at first glance this system appears unnecessarily complicated, it is almost completely automatic in operation, and is provided with necessary alarms to guard against abnormal conditions. In

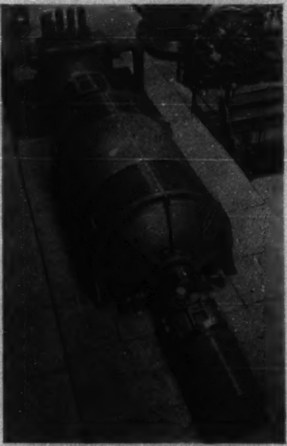

Figure 12. View of the 66,667-kva 3,600-rpm hydrogen-cooled turbogenerator from collector end—Windsor plant of The Ohio Power Company

the event of failure of the vacuum-treating system, a solenoid-operated valve operates automatically to supply oil to the seals from the bearing header of the lubrication system. Such operation results in air being liberated inside the generator which causes a gradual drop in purity, thus necessitating scavenging with pure hydrogen to maintain the gas purity above 90 per cent.

4. *Hydrogen Control and Accessory Equipment—Description*

The equipment for automatically maintaining gas pressure in the generator and for obtaining indications of purity, pressure, and temperature is substantially the same as that used on the synchronous-condenser installations. In the case of a generator the purity indicator becomes an extremely important item, since it is possible for the purity to decrease because of insufficient vacuum treatment of bearing-seal oil, or because of operation of the seals with untreated oil from the bearing header. The purity indicator is of the same type as that used on other hydrogen-cooled machines with the exception that alarm contacts are included to warn of low purity. A fan pressure gauge provides a reliable check on purity when the machine is running.

The hydrogen bottles are located on the turbine floor adjacent to the gas control panel as shown in figure 11, primarily to facilitate scavenging operations with the machine in service. The carbon-dioxide bottles and accessories are located on the operating floor below the generator.

5. *Operating Experience*

Operating experience with this machine has been highly satisfactory. Because of lack of space it is impossible to include this information at this point but it is hoped to present it elsewhere before the Institute.

B. The Windsor Hydrogen-Cooled 66,667-Kva Turbogenerator

1. *General*

This unit located in the Windsor plant of The Ohio Power Company, except for type of coolers, is similar to the Logan machine. A view of this turbogenerator taken from the exciter end is given in figure 12. The outlets for two of the four horizontal coolers can be readily seen. These coolers are similar to the vertical ones previously utilized on synchronous condensers. The accessory equipment is, in practically all respects, the same as at Logan, and the installation is likewise arranged for operation at gas pressures up to 15 pounds per square inch.

2. *Operating Experience*

Operating experience with the Windsor unit has likewise been very satisfactory but for lack of space this information has been deleted.

X. Conclusions and Acknowledgments

A. Conclusions

Operating experience with the eight synchronous condensers described, dating as far back as 1928, and with two hydrogen-cooled alternators, permits the drawing of some rather definite conclusions:

1. Construction for operation in hydrogen is one of the minor factors adversely affecting machine availability. The fact that two machines have each been operating for over two years with no direct supervision indicates that the reliability is as great or greater than that of air-cooled units.

2. From an economic standpoint gas consumption is an almost negligible item. The cost of hydrogen used is generally less than five per cent of the savings obtained by reduction in windage losses.

3. Accessories required for operation in hydrogen have introduced no complications of any significance, and the reliability of this equipment has been fully demonstrated.

4. From a safety standpoint there has appeared no reason for concern when the machine is normally operating in hydrogen. As to the necessary handling of inflammable gas, if reasonable precautions are employed there is considerably less danger involved than is ordinarily taken for granted in connection with operating and maintaining electrical equipment.

5. More than 45 machine years of outdoor operation involving five machines during all possible weather conditions, demonstrate the adaptability of this apparatus for such service.

6. General inspections every five years have been found to be sufficient. Internal difficulties occurring between regular inspections have been reliably and quickly indicated by the various protective devices.

7. Field tests have demonstrated that in general, the air-cooled capacity of a given synchronous condenser can be increased 25 per cent by the utilization of hydrogen, at slightly above atmospheric pressure, and still further augmented an additional 20 per cent by raising the gas pressure to 15 pounds per square inch.

8. When designed for gas pressures up to 15 pounds per square inch, reliable performance can be obtained at such higher pressures, and advantage taken of the additional cooling effects of a hydrogen atmosphere.

9. The utilization of hydrogen, particularly at pressures above atmospheric, permits not only the carrying of additional continuous loads, but also allows heavy swings of short duration with entire safety because of the ability of hydrogen rapidly and efficiently to remove heat from possible hot spots in the windings.

10. The condition of the windings, particularly in the machines which have been in service for over seven years, affords every reason for anticipating insulation life considerably greater than is now obtained from units exposed to the injurious effects of oxidation and corona.

11. It seems clear, to the authors at least, that the hydrogen-ventilated synchronous condenser is preferable and more economical for units above 10,000 kva to the equivalent air-cooled machines. The future offers possibilities of higher voltage and further development at 1,800 or 3,600 rpm to take maximum advantage of hydrogen cooling.

12. Although tests seem to indicate that increases above 15 pounds per square inch do not produce correspondingly proportional gains in cooling or capacity, operation at gas pressures above this level should, and undoubtedly will be explored.

13. The comparatively more limited experience with the hydrogen-ventilated turbogenerators at the Logan and Windsor plants is insufficient safely to draw any conclusions. There is definite reason to believe results which have been obtained with the condensers will be duplicated in the operation of generators which are substantially the same in construction. The only new feature which has been added is the shaft-sealing equipment. This arrangement is still somewhat complicated, but operation on these two units during a combined total of almost two years has demonstrated that these installations as a whole as well as in their component parts, are entirely reliable. As in condensers, the feasibility of using higher gas pressures to obtain greater capacity or to limit maximum permissible heating of the windings, when available cooling water approaches extremely high temperatures, has been demonstrated.

14. Hydrogen cooling permits the construction of large high-speed turbogenerators, which could not be properly cooled by air at all, or in some sizes only by utilizing external fans. By going to hydrogen a more compact design results, which combined with savings from reduced windage losses, more than balances the cost of explosionproof construction and accessories necessary for operation in hydrogen.

15. Judging by the action of the power industry and its engineers, in the past three years, it is increasingly apparent that hydrogen cooling has opened up a new field for the development and design of large capacity and high-speed machines. Hydrogen gas has definitely been accepted by most of the profession associated with power machinery as being the ideal cooling medium for obtaining greater capacity, greater efficiency, and longer life for synchronous condensers, turbogenerators, and for similar large rotative equipment. Hydrogen has become accepted as a cooling medium as matter of factly as its presence in, and as, water.

B. Acknowledgments

The authors wish to acknowledge the fine spirit of co-operation and the vast amount of work carried out by the engineering staffs of both the General Electric Company and the Westinghouse

Electric and Manufacturing Company who between them designed and constructed all the machines discussed in this paper, and their indebtedness to the organizations of the Indiana & Michigan Electric Company, The Ohio Power Company, Appalachian Electric Power Company, The Scranton Electric Company, and the Atlantic City Electric Company, upon whose systems these machines were installed. Had it not been for their patient and sympathetic co-operation in solving all the problems incident to the operation of hydrogen-cooled machines at the time when hydrogen cooling was new and apparently seemed to offer more hazard than benefit, it is doubtful whether the progress made in the last decade in developing hydrogen cooling to the successful point that it has reached today, would have been made as rapidly, if at all.

Theory of Hysteresis-Motor Torque

B. R. TEARE, JR.
MEMBER AIEE

THE object of this study is the development of a quantitative theory of hysteresis-motor torque, especially in relation to magnetic properties and dimensions. The theory is interpreted physically in an idealized case, and applied to a particular motor to verify the result experimentally.

Steinmetz,[1] in 1908, discussed the production of torque by magnetic hysteresis and gave a brief analysis of motor performance. Unpublished experimental studies relating to motor design have been made more recently by other engineers of the General Electric Company, including W. J. Morrill, C. A. Nickle, and R. F. Edgar. The present work was begun while the writer was associated with the last two.

The hysteresis motor consists of a wound stator similar to that of an induction motor; and a rotor composed of laminations of a magnetically hard steel assembled on a nonmagnetic arbor. These elements are shown in figure 1. Stator currents establish a revolving field in the rotor, where hysteresis causes the flux density to lag behind the magnetic intensity. The space phase angle between the stator magnetomotive force and the resultant flux gives rise to an impelling torque, produced without the aid of rotor currents or salient poles. Self-starting, as well as synchronous, the hysteresis motor has been used in phonographs and traffic-signal controls, and, with modifications, in clocks. As Steinmetz[2] pointed out, the torque, efficiency, and power factor compare unfavorably with those of an induction motor; thus the hysteresis motor is not a general competitor, but appears to better advantage as the size decreases.

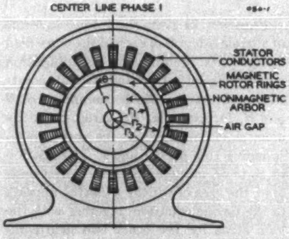

Figure 1. Cross section of hysteresis motor

Derivation of General Torque Equation

A general expression for instantaneous torque in terms of the field within the rotor is obtained from the energy exchange accompanying a virtual angular displacement of the rotor. This method is discussed in many textbooks; for example, the one by Bitter,[3] but expressions directly applicable to the present case are not given.

The stator field and induced rotor magnetization at a given instant are treated as a stationary configuration, the impelling torque due to the field being balanced by an externally applied opposing torque. Each element of volume of the rotor is situated in a magnetic field of strength $\boldsymbol{B}$, which is the sum of $\boldsymbol{B}'$, attributable to the stator alone, and $\boldsymbol{B}''$, to the induced rotor magnetization. The impelling torque may be considered to have its origin in the interaction of $\boldsymbol{B}'$ with the magnetized rotor. To simplify the derivation, the stator is replaced by permanent magnets of appropriate strength and distribution to give an equivalent field $\boldsymbol{B}'$ within the rotor, this substitution being justified by the equivalence between a current circuit and a magnetic shell.[4]

If, by a slight decrease of the opposing torque, the rotor is given a small forward angular displacement $\delta\phi$, the intensity of magnetization $\boldsymbol{M}$ at each point being held constant, mechanical work of amount $T\delta\phi$ is done at the expense of the magnetic energy of the system, thus,

$$T\delta\theta = -\delta W \tag{1}$$

In this and succeeding equations, centimeter-gram-second electromagnetic units are employed. Since $\boldsymbol{M}$ is constant, the

B. R. Teare, Jr., is professor of electrical engineering, Carnegie Institute of Technology, Pittsburgh, Pa.

The author is indebted to P. L. Alger and R. F. Edgar of the General Electric Company for their counsel and for the experimental motor, and to Professors H. M. Turner and D. V. Ver Planck of Yale University for their criticisms of the written presentation. This paper is part of a dissertation submitted for the degree of doctor of engineering, Yale School of Engineering.

1. For all numbered references, see list at end of paper.

only portion of the energy which changes is that associated with the interaction of the rotor magnetization and the stator field. On the basis of Ampere's theory of magnetism,[4] this energy for any volume element dV is given in terms of components by

$$dW=-(M_rB_r'+M_\theta B_\theta'+M_zB_z')dV \qquad (2)$$

where r, θ, and z are cylindrical co-ordinates, fixed with respect to the stator, and shown in figure 1. The displacement moves the volume element to a position where the field components are $B_r'+(\partial B_r'/\partial\theta)\delta\phi$, $B_\theta'+(\partial B_\theta'/\partial\theta)\delta\phi$, etc.; thus the energy of the element decreases by the amount:

$$-\delta(dW)=[M_r(\partial B_r'/\partial\theta)+M_\theta(\partial B_\theta'/\partial\theta)+M_z(\partial B_z'/\partial\theta)]\delta\phi dV \qquad (3)$$

Integration over the volume V of the rotor gives:

$$-\delta W=\delta\phi\int\int\int_V[M_r(\partial B_r'/\partial\theta)+M_\theta(\partial B_\theta'/\partial\theta)+M_z(\partial B_z'/\partial\theta)]dV \qquad (4)$$

On substituting this expression in equation 1, dividing both members by $\delta\phi$, and writing dV in terms of the co-ordinates, there results:

$$T=\int_0^L\int_{r_1}^{r_2}\int_0^{2\pi}[M_r(\partial B_r'/\partial\theta)+M_\theta(\partial B_\theta'/\partial\theta)+M_z(\partial B_z'/\partial\theta)]rd\theta drdz \qquad (5)$$

where L is the length of the rotor.

Equation 5 can also be obtained by an alternative procedure which makes use of a general expression[5] for the torque on a magnetized body, and does not require a virtual displacement, or the substitution of permanent magnets for the stator.

An equation giving torque in terms of the total field $\boldsymbol{B}$, instead of $\boldsymbol{B}'$, is more convenient for application. The other part of the field, $\boldsymbol{B}''$, which arises from the magnetization of the rotor itself, produces only pairs of equal and opposite torques, the actions and reactions between magnetic elements. Thus, if an external field identical with $\boldsymbol{B}''$ were impressed on the rotor, the torque would be zero, or

$$0=\int^L\int_{r_1}^{r_2}\int_0^{2\pi}[M_r(\partial B_r''/\partial\theta)+M_\theta(\partial B_\theta''/\partial\theta)+M_z(\partial B_z''/\partial\theta)]rd\theta drdz$$

If this equation is added to 5, there results:

$$T=\int_0^L\int_{r_1}^{r_2}\int_0^{2\pi}[M_r(\partial B_r/\partial\theta)+M_\theta(\partial B_\theta/\partial\theta)+M_z(\partial B_z/\partial\theta)]rd\theta drdz \qquad (6)$$

In each term the component of $\boldsymbol{B}$ may be used as the variable of integration in place of θ, and since $\boldsymbol{B}$ and $\boldsymbol{M}$ go through a cycle of values in twice the pole pitch of the stator winding, the integral around the rotor may be expressed in terms of the cyclic integral, thus,

$$T=p/2\int_0^L\int^{r_2}\oint(M_rdB_r+M_\theta dB_\theta+M_zdB_z)rdrdz \qquad (7)$$

in which p is the number of poles. Each integration of MdB is to be performed in the direction of positive θ. The torque may be expressed in terms of magnetic intensity $\boldsymbol{H}$ instead of $\boldsymbol{M}$ by using the relation

$$\boldsymbol{M}=(\boldsymbol{B}-\boldsymbol{H})/4\pi \qquad (8)$$

For the r term,

$$\oint M_rdB_r=1/4\pi\oint B_rdB_r-1/4\pi\oint H_rdB_r$$
$$=-1/4\pi\oint H_rdB_r \qquad (9)$$

since $\oint B_rdB_r$ vanishes for integration over a cycle.

If the last member of equation 9 is integrated by parts

$$\oint M_rdB_r=-1/4\pi H_rB_r+1/4\pi\oint B_rdH_r$$
$$=1/4\pi\oint B_rdH_r$$

since H_rB_r has the same value at the beginning and end of one cycle. After a similar treatment of the other terms, equation 7 becomes

$$T=p/8\pi\times$$
$$\int_0^L\int^{r_2}\oint(B_rdH_r+B_\theta dH_\theta+B_zdH_z)rdrdz \qquad (10)$$

Equation 10 gives the torque in terms of a triple integral of each of the three field components, requiring for its application a knowledge of both $\boldsymbol{B}$ and $\boldsymbol{H}$ at all points within the rotor. Each component of $\boldsymbol{B}$ and $\boldsymbol{H}$, for example, B_θ, varies cyclically along a circular arc of the rotor corresponding to a fixed r and z. The relation of B_θ to H_θ is represented by a hysteresis loop, the area of which, $\oint B_\theta dH_\theta$, appears in the torque equation, together with the loop areas for the other two field components. In general all three loops vary with r and z.

For some applications equation 10 may be simplified. Thus, if the axial component of the field is negligible, the last term of the integrand may be dropped, the other components are independent of z, and

$$T=(pL/8\pi)\int_{r_1}^{r_2}\oint r(B_rdH_r+B_\theta dH_\theta)dr \qquad (11)$$

Also, it can be shown, from the expression for the magnetic field, that as the radial thickness of the rings is decreased; that is, as r_1 approaches r_2, the radial component of the field decreases, and the tangential field becomes independent of r. For sufficiently thin rings the radial component may be dropped from the equation, and the remaining integral written as the product of two factors; thus, after multiplication and division by 2π,

$$T=[p/(16\pi^2)](L\int_{r_1}^{r_2}2\pi rdr)\oint B_\theta dH_\theta$$
$$=pV/(16\pi^2)\oint B_\theta dH_\theta$$
$$=K\oint B_\theta dH_\theta \qquad (12)$$

where V is the volume of the magnetic material in the rotor, and K, a constant for a particular motor.

The motor used in the experimental verification of the theory has dimensions r_1 and r_2 such that the tangential component varies but little with r, as shown in figure 6, but the radial component is large enough to contribute up to 10 per cent of the total torque. The contribution from the former is calculated from equation 12 in which B_θ is replaced by its average $\overline{B}_\theta$, taken with respect to r. Since the relatively small torque T_r, from the radial component, need not be determined accurately, r is replaced by its mean value, $^1/_2(r_1+r_2)$, and

$$T_r=[pL/(16\pi^2)][2\pi(r_1+r_2)/2]\times\int_{r_1}^{r_2}\oint B_rdH_rdr \qquad (13)$$

Here the integral is the average value of $\oint B_rdH_r$ with respect to r, multiplied by the radial thickness (r_2-r_1); hence,

$$T=[pL/(16\pi^2)][\pi(r_2+r_1)(r_2-r_1)]\overline{\oint B_rdH_r}$$
$$=K\overline{\oint B_rdH_r} \qquad (14)$$

where the bar denotes the average of the whole integral. Thus the total torque of the experimental motor is given by:

$$T=K[\oint\overline{B_\theta}d\overline{H_\theta}+\oint\overline{B_rdH_r}] \qquad (15)$$

Physical Interpretation of the Torque Equation

For illustration the theory will be applied to a simple type of motor having such relative dimensions that equation 12 is appropriate. It is assumed that the revolving stator magnetomotive force is sinusoidal, and that the air gap reluctance is large compared to that of the rotor. Thus the rotor flux density will be tangential, varying sinusoidally with θ, and independent of r.

When the rotor turns at less than synchronous speed, any element of volume moves with respect to the field and experiences a sinusoidal variation of B in time, eventually reaching a cyclic state in which corresponding values of B and H are given by an alternating hysteresis loop, such as shown in figure 2. Other elements of volume go through exactly similar magnetic cycles, displaced in time phase; thus the loop gives either the time variation of the magnetic state at a fixed point on the rotor, or the space variation around the rotor at a particular instant of time. According to the latter interpretation, the area, A, of the loop is the integral $\oint B_\theta dH_\theta$ required in equation 12, and

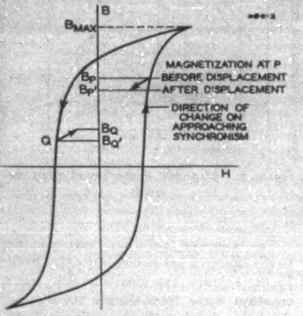

Figure 2. Instantaneous B-H relation around rotor

$$T = KA \qquad (16)$$

The torque is the same from zero to synchronous speed, a fact noted by Steinmetz.[1]

Torque at Synchronous Speed

When the motor is accelerating to synchronous speed, the rotor slips backward with respect to the rotating field at a diminishing rate. The field at a given point P goes through its magnetic cycle, figure 2, more and more slowly, until at synchronism, the flux density reaches the value B_P and momentarily stops changing. Depending upon the location of P with respect to the flux density wave, the last change of B may have been an increase or a decrease; if the former, B_P lies on the ascending branch of the hysteresis loop. At another point Q, where the last change of B was a decrease, B_Q lies on the descending branch. The relation of B to H around the rotor, at the instant when it has synchronous speed, is still given by figure 2, and the impelling torque is the same as at subsynchronous speeds. If, at this instant, the load torque is just equal to the impelling torque, the motor speed will not change any further, and the motor will operate steadily at synchronous speed.

However, if the load torque is less than the impelling torque, there will be a further increase of speed and a displacement of the rotor forward with respect to the field. Such a relative movement is in the opposite direction to that last occurring, hence the field at P, reached by an increase, now decreases to B_P', the change of state occurring on a minor loop. Thus, after a forward displacement, the B-H relation from point to point around the rotor is given by a closed curve which is similar to the original hysteresis loop and derived from it by a displacement of all its points inward along their respective minor loops. The new loop is smaller and the torque less than before. Such B-H loops are shown in figure 3. These were obtained graphically, the minor loops being taken as straight lines, all having the slope of the descending branch of the major loop at its tip. On this basis the torque decreases linearly with displacement angle, but if the true minor loops are used, the relationship is nonlinear and multivalued. Thus as the forward displacement increases, the impelling torque decreases and at some point is in equilibrium with the load. However, the rotor speed is greater than synchronous, and so the displacement continues to increase, the net torque becoming negative, or retarding. The relation between net torque and displacement is such that the rotor oscillates about the equilibrium point, with decreasing amplitude because of losses. When the oscillations have decreased to zero the rotor turns uniformly at synchronous speed, and has a position with respect to the field that makes the impelling torque just equal to the load. At no load the position is such that the area of the B-H loop is zero. If an external driving torque is applied the further displacement interchanges the ascending and descending branches, giving a negative area integral, which corresponds to generator action.

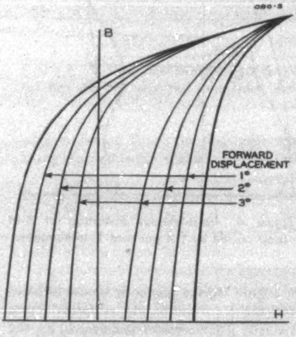

Figure 3. B-H loops for decreased loads. Angular displacement referred to B

The speed-torque characteristic is similar to that of a synchronous motor whose field-pole structure can slip on the shaft when the torque reaches a sufficiently high value. For the purposes of analogy, the friction torque during slipping is constant, is equal to the maximum static friction, and both are less than the magnetic pull-out torque. When the shaft slips, turning at less than synchronous speed, the output torque is that of constant friction; but at synchronous speed the torque has any positive or negative value up to this magnitude, depending upon the angle between the poles and the rotating magnetomotive force, and hunting can occur.

Effect of Harmonics

The effect of field harmonics on torque may be determined from their modification of the B-H loop. The effect depends upon whether the harmonics move at the same speed as the fundamental, or at different speeds; hence two types of field must be considered.

The first, in which the resultant field has a constant wave form, may be produced by the magnetic nonlinearity of the rotor, or by mechanically turning the stator, it being excited by direct current and having a nonsinusoidal magnetomotive force. If the harmonic amplitudes are so small that they do not introduce additional maxima and minima in the flux-density wave, the B-H relation is still a hysteresis loop, the same as the one for the fundamental alone (figure 2), except for a possible change in tip value depending upon the phases and amplitudes of the harmonics. Hence, in this case the harmonics have little or no effect on the torque.

The second type of field, in which the harmonics move relatively to the fundamental, is produced by polyphase a-c excitation, the stator windings being distributed in slots. When the rotor turns at synchronous speed, the field at any volume element P consists of the periodically varying resultant of harmonics superposed on the constant local value of the fundamental. The modification of the B-H relation is illustrated in figure 4, where point p gives the flux density B_P at P, in the absence of harmonics. Let the harmonic variation be introduced in such a way that at P it is initially zero, then increases to a maximum, B_h, decreases to $-B_h$, etc., periodically. The first change from zero to B_h occurs on line pq, and that from $+B_h$ to $-B_h$ on line qs. The latter is also the locus of all subsequent variations if the width of the minor loop and its change of position with cyclic repetition are neglected. No matter how the harmonics are introduced, the final cyclic variation of B with respect to H occurs on the minor loop which intersects the major loop at the sum of the local value of the fundamental and the maximum of the harmonics. The major loop is that one whose tip flux density is the maximum of the total field.

At volume elements other than P there are similar variations, except for phase. Hence at any instant the harmonics cause a wave-like indentation of the major loop, shown for a single harmonic, the 11th, in the figure. In this case the indentations have a maximum of twice the harmonic amplitude and travel around the loop in time. The corresponding instantaneous torque at synchronous speed is given by equation 16 in which A is the area of the indented loop. The average torque can be found by averaging the loop area with respect to time, or by using the loop drawn through the centers of the minor loops, such as point r in figure 4. Such a loop is similar, but not identical, to the ones of figure 3. The reduction of area depends upon the amplitude of the harmonic and the slope of the minor loop, or incremental permeability.

When more than one harmonic is present the modification due to the resultant must be determined. In general the effect of a number of harmonics is not the sum of their individual effects.

The torque at subsynchronous speeds can be found from a similar analysis, but in this case the variation at each volume element due to the fundamental must also be considered.

Application of Theory to Experimental Motor

The theory is applied to the four-pole motor shown in figure 1, and for which data are given in table I. There are four different sets of rotor rings, one of 36 per cent cobalt steel, and three of 3 per cent chrome steel with different air gaps. The motor differs from commercial shaded-pole types in having a distributed stator winding, which simplifies the calculation.

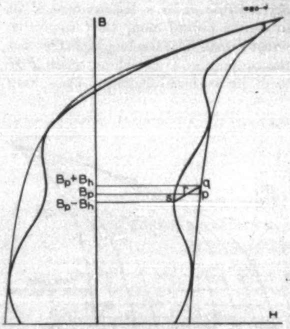

Figure 4. Instantaneous distortion of B-H loop caused by 1.2 per cent 11th harmonic

Figure 5 gives magnetic characteristics for the rotor materials, obtained from ballistic galvanometer tests made on the rings. The characteristics include the normal and incremental permeabilities, and the hysteresis loss per unit volume per cycle, the last being $^1/_{4\pi}$ times the loop area. The incremental permeability is that for small changes at the tip of the major loop. Separate curves are given for the largest chrome-steel rotor since its heat treatment is different.

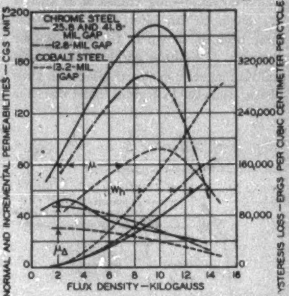

Figure 5. Magnetic properties of rotor materials

Two kinds of operation, corresponding to the effects of harmonics, are considered. In the simpler, the magnetic field has a constant wave form during its motion, this being simulated by exciting one winding with direct current, and driving the rotor with an external motor. The harmonics are small enough so that they have a negligible effect on maximum flux density and torque.

The distribution of the magnetic field and its strength in relation to current are first determined, and then the corresponding torque. For the sake of brevity only an outline of the procedure is given.

The following assumptions are made to permit and facilitate analytical treatment:

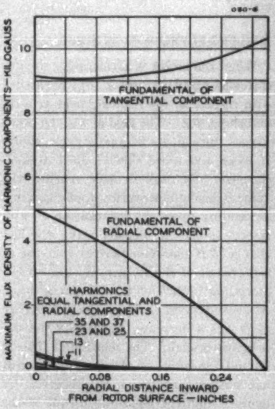

Figure 6. Calculated amplitudes of field components

Chrome-steel rotor, 12.8-mil gap, $\mu = 150$, $\mu_\Delta = 27$

1. The field is two dimensional; the axial component, due to fringing at the ends, being neglected.

2. There are no magnetomotive-force drops in the stator laminations.

3. There are no eddy currents in the laminated rotor.

4. The tangential component of H at the stator boundary is a rectangular wave. This is expressed as a Fourier series, and in the experimental motor the winding is so distributed that the only harmonics present are those of order 1, 11, 13, 23, 25, etc.

5. The field in the arbor supporting the rotor rings is negligible, due to magnetic shielding by the more permeable rotor steel.

6. In calculating the fundamental components of B and H in the rotor, the hysteresis loop is replaced by an inclined ellipse, which has the same maximum values of B and H, and the same area as the alternating loop. The geometric shape factors of the ellipse, the ratio of B_{max} to H_{max} and the phase angle between B and H, are determined to correspond to the tangential flux density averaged over the section, and then treated as if independent of the variations of the field with r.

7. In calculating the harmonics at synchronous speed, the incremental permeability, μ_Δ, the slope of the minor loops, is taken as constant; and for simplicity the slope of the descending branch of the major loop at its tip is used.

The procedure of determining the magnetic field consists of finding solutions of the field equations,

$$\nabla \cdot \boldsymbol{B} = 0 \qquad (17)$$

$$\nabla \times \boldsymbol{H} = 0 \qquad (18)$$

separately for the regions of air gap and rotor rings, and then assigning values to the undetermined constants to satisfy assumptions 4 and 5, and the conditions of continuity for $\boldsymbol{B}$ and $\boldsymbol{H}$ at the common boundary. The fundamental component of the field in the air gap and, by virtue of assumption 7, the harmonics in both regions are solutions of Laplace's equation, the method and results being given, for example, by Doherty and Nickle.[6] A modification of this method is used to determine the fundamental within the rotor rings, to conform to assumption 6; but the result is similar, except for a phase angle, to that obtained when B is proportional to H.

At any point within the rotor, the radial and tangential components of the density are expressible as the sum of harmonic terms, the amplitudes of which vary with r, and can be computed from the dimensions, current, and magnetic data. Typical values, as functions of r, are shown in figure 6. While the radial and tangential components of the fundamentals differ markedly, those for any harmonic are equal.

In the case of the fundamental, the field calculations agree reasonably well with measurements, as shown for three different air gaps in figure 7. The measured values are obtained from the electromotive force generated in an exploring turn of fine wire enclosing the rotor rings, the rotor being turned with respect to the field. The agreement is improved if, to allow for the decreased permeability of the stator laminations caused by punching, an effective air gap two mils larger than the nominal one is used in the calculation.

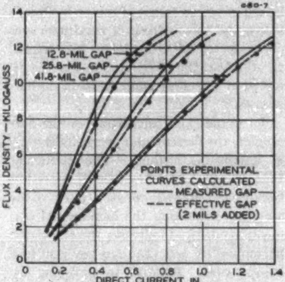

Figure 7. Fundamental component of tangential flux density averaged over radial depth

In the case of harmonics, the agreement is not nearly so good. The measured amplitude of the 11th is about twice that calculated; and the 13th, which should be nearly equal to the 11th, is scarcely present. The resultant of the two, averaged with respect to r and θ, which is required in the second torque determination, is approximately 25 per cent higher than the calculated values.

The flux density, which can be related to current, determines the area of the B-H loop, and, by equation 15, the torque. In the first case, when the field has a constant wave form, harmonics are neglected, since they increase the average tangential flux density by less than two per cent. (They contribute more to the radial flux density, as shown in figure 6, but the latter gives rise to only ten per cent, or less, of the total torque, and hence need not be calculated as accurately.) The results of the torque calculation are given in figure 8, also the measured torques, obtained from the force required to balance the stator in a ball-bearing dynamometer mounting.

In the second case, with a-c excitation and operation at synchronous speed, the torque attributable to the tangential field is calculated from the area of the alternating loop as reduced by harmonic displacements along minor loops. Only the two most important harmonics, the 11th and 13th, are included and the resultant of these is averaged with respect to r, θ, and time to obtain an equivalent constant uniform indentation of the major loop. The torque attributable to the radial field is reduced in greater proportion since harmonics of the same amplitude are superposed upon a smaller fundamental, hence this part of the torque, small in the absence of harmonics, is now neglected. Calculated and measured values are shown in figure 9.

Discussion of Results

The difficulties in applying the theory arise chiefly in the inherently nonlinear characteristic of the rotor material. Hence the calculations are more accurate for the larger air gaps, where the rotor characteristic has less effect, and for weak fields, in which the nonlinearity is less pronounced.

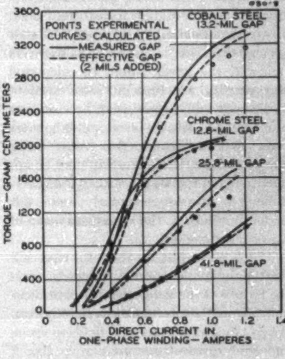

Figure 8. Maximum torque, field of constant wave form

The assumptions and approximations are to simplify the calculations, and to supply information not otherwise available. On the basis of experimental and theoretical evidence, assumptions 1, 3, 4, and 5 are believed to introduce little error. The discrepancy between measured and calculated flux density (figure 7) is attributed to the inaccuracy of assumption 2 arising from the decrease of permeability near the edge of the laminations by the mechanical strain of punching. Motor designers sometimes make allowance for this by increasing the measured gap by about

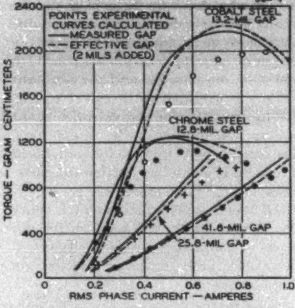

Figure 9. Maximum torque at synchronous speed, balanced two-phase excitation

four mils for the purpose of calculations. Similar effects have been reported by H. M. Turner[7] for a butt joint between sections of a laminated transformer core, where the apparent air gap was four mils greater than that measured. As shown in figure 7, the lower values of calculated flux density are brought into excellent agreement with experiment by using an effective gap which is two mils greater than that measured, this value being chosen because the correction need be applied only to the stator. Also, the gap is difficult to measure accurately, and is not perfectly uniform, the variations being of the order of one mil.

The *B-H* relation for the rotor material, treated in assumption 6, depends upon the nature of the field, and differs at most points from the alternating hysteresis loop. When two equal sinusoidal fields in space and time quadrature combine to give a rotating field of constant magnitude, the *B-H* relation for each component is an ellipse,[8] the area of which at first increases with flux density, then reaches a maximum, and finally decreases to zero at saturation. In the hysteresis motor the fundamental of the field is predominantly alternating; but, because of the radial component, also has a rotating constituent, which varies from zero at the inner rotor boundary to equality with the alternating constituent at the outer one. For a field that has both constituents, the *B-H* relation is not exactly known. At synchronous speed, moreover, it will be modified by the varying harmonics. Spooner[9] has shown that the effect of harmonics in the same direction as the fundamental can be explained in terms of minor hysteresis loops, and this analysis of maximum synchronous torque is similar to his method. In addition, the *B-H* relation may be affected by the cross components of the harmonics.[10]

To permit the calculation of the harmonics, the incremental permeability, μ_Δ, is assumed constant. The particular value chosen has little effect on the result, because of the predominating effect of the air gap; increasing the incremental permeability tenfold increases the calculated harmonics by less than ten per cent in a typical case. Relative to assuming the same incremental permeability for all the minor loops on a given major loop, measurements show the same proportionate error in the harmonics at high flux densities, where the variation of μ_Δ is seven to one, as at low ones, where it is only two to one. However, the use of linear approximations in treating the nonlinear motor must be the ultimate source of the discrepancy between the calculated and the experimental values of the harmonics, since there is agreement when a nonmagnetic material is substituted. The use of averages introduces no new approximations after linearity has been assumed.

Conclusions

This study provides a general relationship between hysteresis torque and magnetic field which can be used to predetermine hysteresis motor performance. It is shown that the torque depends not only on the area of the hysteresis loop, but also when harmonics are present, on the incremental permeability, a rotor material with high incremental permeability being most desirable. It is important to design the stator windings to minimize harmonics as far as possible.

The application of the theory gives a test of its accuracy, an indication of its applicability, and the relative numerical magnitudes of the quantities involved. The greatest discrepancy between predicted and measured torques was found to be 20 per cent, and this is believed to have its principal source in the approximations made to deal with nonlinear characteristics, especially for calculating the harmonics. In the case of shaded-pole motors, which have relatively larger harmonics, the difficulties would be greater and the calculations correspondingly less accurate. The application also indicates the need for more complete data than are available, particularly the *B-H* relations when rotating harmonics are superposed on a constant field.

Starting Performance of Salient-Pole Synchronous Motors

M. M. LIWSCHITZ
MEMBER AIEE

IN recent years, two papers on the subject of salient-pole synchronous motors have been published in which practical methods for calculating the starting performance are derived on the basis of considerations that take into account all the unsymmetrics of this type of machine; the authors of these two papers are respectively H. V. Putman and T. M. Linville. Application of the Putman method gives at small values of the slip torque values that are somewhat too high; on the other hand, application of the Linville method is rather laborious, especially when the damper cage has a relatively large number of bars per pole. In view hereof, the author presents in this paper another method of calculating the starting performance of a salient-pole synchronous motor, a method which also takes into consideration all the unsymmetrics of this machine. This new method is, on the one hand, much simpler to apply than the Linville method, while on the other hand, it leads to more accurate results than the Putman method. It has been used for many years in the calculation and design of machines of various ratings and speeds, and has always given satisfactory results.

General Method of Calculation; Equivalent Flux Waves and Circuits

The assumption will be made that magnetic saturation can be neglected. It is then possible to superimpose the five fluxes set up by the five-winding systems of the three-phase machine. In doing this, only the fundamentals of these five fluxes will be taken into consideration.

The five fluxes just referred to will be replaced by two other fluxes which are stationary with respect to the field structure and whose axes coincide respectively with the center lines of the poles and with the center lines of the interpolar gaps. Furthermore, the unsymmetrical damper winding will be replaced by two single-axis windings whose axes also coincide respectively with the center lines of the poles and with the center lines of the interpolar gaps.

An illustration of this procedure is given in figure 1, which relates to a damper winding having six bars per pole; the two pulsating fluxes B_d (direct-axis flux) and B_q (quadrature-axis flux) are shown in figure 1*a*, and the two equivalent single-axis damper windings in figures 1*b* and 1*c*. It follows from figure 1*a* that the direct-axis flux produces in two damper bars that are located symmetrically with respect to the center line of the pole, currents of equal magnitude and of opposite direction, while it produces in two damper bars that are located symmetrically with respect to the center line of the interpolar gap, currents of equal magnitude and of equal direction. It is clear, therefore, that there cannot flow any currents induced by the direct-axis flux in the end-ring segments that connect together bars located in adjacent pole shoes, and that by virtue hereof the cage may be replaced by a winding arranged as per figure 1*b* as long as only the effect of the direct-axis flux is being considered. The quadrature-axis or cross flux, however, induces currents of equal magnitude and opposite direction in two damper bars that are located symmetrically with respect to the center line of the interpolar gap, and currents of equal magnitude and equal direction in two damper bars that are located symmetrically with respect to the center line of the pole. This means that the currents flowing through the damper bars in one-half of a pole shoe cannot take a return path through the damper bars in the other half of the same pole shoe, and that it is possible, therefore, to replace the damper cage by a winding as per figure 1*c* as long as only the effect of the quadrature-axis flux is being studied. Thereupon the resultant currents may be obtained by superposition, by virtue of the fact that the differential equations governing the current components are linear.

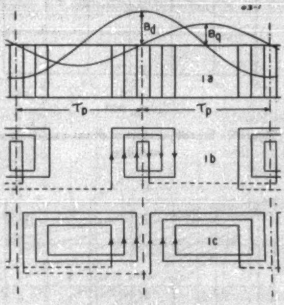

Figure 1. Direct-axis damper winding and quadrature-axis damper winding

The bars of the equivalent damper windings, figures 1*b* and 1*c*, are all connected in series, and this might be construed as being an indication that all these bars carry current of equal magnitude. This, however, is not in accordance with the facts, so that it becomes necessary to introduce appropriate breadth factors in order to take into account the actual conditions of current flow. If the new calculation method, when applied to the special case of an ordinary polyphase induction motor with squirrel-cage rotor, gives correct results, this may be considered as a criterion of the correctness of the method in general. It can be readily proved that in the case just referred to the results will be correct, that is, that the results obtained by calculating said induction motor as a machine having two equivalent rotor windings as per figure 1 will be the same as those obtained by the customary method of calculating the machine.

When the cage bars belonging to one and the same pole have not all the same resistance, they must be replaced by "equivalent" cage bars having all identically the same resistance over the entire pole width, whereupon the two single-axis damper windings as per figures 1*b* and 1*c* must be assumed to be formed by these "equivalent" cage bars.

In calculating the machine upon the introduction of those two single-axis damper windings, it can be taken into account that the winding as per figure 1*c* will have longer end turns than the winding as per figure 1*b*. Usually, however, this difference in end-turn length will be negligible, because in synchronous motors the resistances of the ring-segments are nearly negligible in comparison with the cage-bar resistances.

The equivalent single-axis damper wind-

Paper 40-3, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted October 13, 1939; made available for preprinting December 6, 1939; released for final publication March 4, 1940.

M. M. Liwschitz is consulting engineer, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

ing as per figure 1*b* will be called the direct-axis damper winding and will be designated by D_d, while the winding as per figure 1*c* will be called the quadrature-axis damper winding, designated by D_q.

It is shown in appendix I that the breadth factors of the two equivalent single-axis damper windings are equal to:

$$\xi_{Dd}=\frac{\sin\left(\frac{q_p-1}{4}\alpha\right)\sin\left(\frac{q_p+1}{4}\alpha\right)}{(q_p-1)\sin\frac{\alpha}{2}}\quad \text{for } q_p=\text{odd} \tag{1}$$

$$\xi_{Dd}=\frac{\sin^2\frac{q_p}{4}\alpha}{q_p\sin\frac{\alpha}{2}}\quad \text{for } q_p=\text{even} \tag{2}$$

$$\xi_{Dq}=\frac{\sin\frac{q_p}{2}\alpha}{2q_p\sin\frac{\alpha}{2}}\quad \text{for } q_p=\text{odd and even} \tag{3}$$

if q_p designates the number of damper bars per pole, and α the angle between two adjacent damper bars in electrical degrees. Using further the symbols whose meanings are given in the list of symbols found at the end of this paper, the factors to be introduced in order to reduce the damper windings to terms of the primary are found to be equal to:

$$\frac{m_1}{4p(q_p-1)}\left(\frac{w_1\xi_1}{\xi_{Dd}}\right)^2 \quad \text{for } q_p=\text{odd, or}$$

$$\frac{m_1}{4pq_p}\left(\frac{w_1\xi_1}{\xi_{Dd}}\right)^2 \quad \text{for } q_p=\text{even}$$

for one bar of the direct-axis winding, and to

$$\frac{m_1}{4pq_p}\left(\frac{w_1\xi_1}{\xi_{Dq}}\right)^2 \quad \text{for } q_p=\text{odd and even}$$

for one bar of the quadrature-axis winding, p representing in either case the number of pairs of poles.

The breadth-factors ξ_{Dd} and ξ_{Dq} are represented in the figures 2 and 3 as functions of the angle α and for different values of q_p.

Torques and Current Equations

It will be shown in appendix *B* how in the first place the two fluxes B_d and B_q can be determined on the basis of certain simplifying assumptions, how subsequently the currents induced by these fluxes in the two single-axis damper windings can be calculated, and how finally the torque developed by the machine can be found. All quantities appearing in the final equations are per-unit quantities, unit voltage being the normal or rated phase voltage, unit current the current, and unit torque the torque corresponding to the normal or rated three-phase output, unit impedance the impedance through which unit current will be caused to flow by the rated voltage at the rated frequency. Using said per-unit quantities, the following simple expression for the torque is obtained:

$$T=\frac{1}{2}\left[\frac{\frac{r_{2d}}{s}}{\left[r_1+(1+\tau_{1d})\frac{r_{2d}}{s}\right]^2+[x_1+(1+\tau_{1d})x_{2d}]^2}+\frac{\frac{r_{Dq}}{s}}{\left[r_1+(1+\tau_{1q})\frac{r_{Dq}}{s}\right]^2+[x_1+(1+\tau_{1q})x_{Dq}]^2}\right] \tag{4}$$

The symbols appearing in this expression are partly explained in the list of symbols partly given in the equivalent circuit diagrams represented in figure 4 (direct-axis diagram) and figure 5 (quadrature-axis diagram).

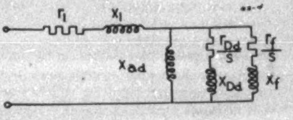

Figure 4. Equivalent circuit for direct axis

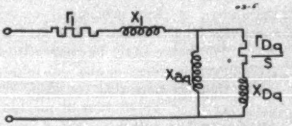

Figure 5. Equivalent circuit for quadrature axis

The expression for the current can be written as follows:

$$I=\frac{1}{2}\left[\sqrt{\frac{f_d^2+h_d^2}{k_d^2+l_d^2}}+\sqrt{\frac{f_q^2+h_q^2}{k_q^2+l_q^2}}\right]\times\cos\phi\times\eta \tag{5}$$

in which:

$f_d=1+\tau_{2d}$ $\qquad$ $f_q=1+\tau_{2q}$

$h_d=-\frac{\frac{r_{2d}}{s}}{x_{ad}}$ $\qquad$ $h_q=-\frac{\frac{r_{Dq}}{s}}{x_{aq}}$

$k_d=r_1+(1+\tau_{1d})\frac{r_{2d}}{s}$ $\qquad$ $k_q=r_1+(1+\tau_{1q})\frac{r_{Dq}}{s}$

$l_d=x_1+(1+\tau_{1d})x_{2d}$ $\qquad$ $l_q=x_1+(1+\tau_{1q})x_{Dq}$

while k_d, l_d, k_q, and l_q are the same quantities which appear in the denominator of T. Since the expression for the current has been multiplied with the product $\cos\phi\times\eta$, it gives the current expressed in the unit input-current.

The calculated and the measured torques for two different machines are represented on a comparative basis in the figures 6 and 7, while for one of these machines the calculated and measured current values are also given. It will be noted that in figure 6, the calculated torque values do not check so very well with the tested values when the slip is small. It should be noted that in many instances the discrepancies between calculated and tested values will be smaller than in figure 6, although occasionally they will be still larger. Those who are intimately acquainted with the subject in question will readily admit that it is

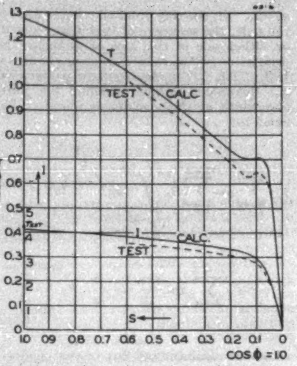

Figure 6. Calculation and test comparison for a synchronous motor, 780 horsepower, 32 poles

very difficult to take properly into account all the factors that affect the starting performance of a synchronous machine with salient poles.

It is equally possible to calculate on the basis of the equivalent circuit diagrams figure 4 and figure 5, the torque and the current by the method followed by Linville. The latter method is based on certain formulas derived by Park, and gives separately the forward current and the backward current [the latter current having the frequency $(2s-1)f_1$]. The forward current is found to be equal to:

$$I_f = \frac{1}{l^2+m^2}\sqrt{f^2+g^2}\cos\phi\times\eta \tag{6}$$

the backward current is found to be equal to:

$$I_b = \frac{1}{l^2+m^2}\sqrt{f'^2+g'^2}\cos\phi\times\eta \tag{7}$$

and for the torque the expression is found:

$$T = \frac{f}{l^2+m^2} - I_f^2 r_1 - I_b^2\frac{r_1}{1+2s} \tag{8}$$

in which:

$$r_{cd} = x_{ad}^2\frac{\dfrac{r_{3d}}{s}}{\left(\dfrac{r_{3d}}{s}\right)^2+[(1+r_{3d})x_{ad}]^2}$$

$$x_{cd} = \frac{x_{3d}x_{ad}^2+x_{ad}\left[\left(\dfrac{r_{3d}}{s}\right)^2+x_{3d}^2\right]}{\left(\dfrac{r_{3d}}{s}\right)^2+[(1+r_{3d})x_{ad}]^2}$$

$r_d = r_{cd}+r_1 \qquad x_d = x_{cd}+x_1$

$$r_d' = r_d+2r_1\frac{1-s}{2s-1}$$

$$r_{cq} = x_{aq}^2\frac{\dfrac{r_{Dq}}{s}}{\left(\dfrac{r_{Dq}}{s}\right)^2+[(1+r_{3q})x_{aq}]^2}$$

$$x_{cq} = \frac{x_{Dq}x_{aq}^2+x_{aq}\left[\left(\dfrac{r_{Dq}}{s}\right)^2+x_{Dq}^2\right]}{\left(\dfrac{r_{Dq}}{s}\right)+[(1+r_{1q})x_{aq}]^2}$$

$r_q = r_{cq}+r_1 \qquad x_q = x_{cq}+x_1$

$r_q' = r_q+2r_1\dfrac{1-s}{2s-1} \qquad a = r_d r_q' - x_d x_q$

$c = r_d' r_q - x_d x_q \qquad l = a+c$

$b = x_d r_q' + x_q r_d \qquad d = x_d r_q + x_q r_d'$

$m = b+d \qquad R = r_q' + r_d'$

$f = Rl + xm \qquad R' = r_q' - r_d'$

$f' = R'l + xm' \qquad x = x_q + x_d$

$g = xl - Rm \qquad x' = x_q - x_d$

$g' = x'l - R'm$

Using the following abbreviations:

$r_t = r_d + r_q \qquad x_t = x_d + x_q$

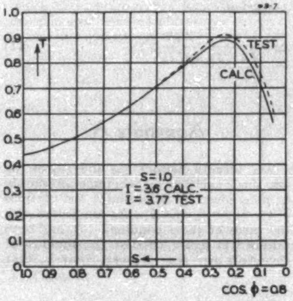

Figure 7. Calculation and test comparison for a synchronous motor, 1,200 horsepower, 56 poles

the following expressions for the currents and for the torque at one-half the synchronous speed ($s=0.5$) are obtained:

$$I_f = 2\frac{1}{\sqrt{r_t^2+x_t^2}}\cos\phi\times\eta$$

$$I_b = 0$$

$$T = \frac{2}{\sqrt{r_t^2+x_t^2}} - I_f^2 r_1$$

Influence of the D-C Excitation

Of considerable interest is the influence of the d-c excitation on the starting performance. The d-c excitation has the effect of producing a negative torque, that is, a torque which seeks to decelerate the rotor during start and which is the cause of the occurrence of "negative damping" in a synchronous machine. It will be shown in appendix *C* that the torque produced by the d-c excitation is given by the equation:

$$T_f = -\left(\frac{E}{U}\right)^2\frac{r_1[r_1^2+(1-s)^2x_q^2](1-s)}{[r_1^2+(1-s)^2x_dx_q]^2} \tag{9}$$

This torque, which is negative over the entire starting period, has a maximum in the neighborhood of the standstill point, and the magnitude which the slope of the curve representing this torque has in the neighborhood of the synchronous point is a measure of the "negative damping torque" of the synchronous machine. This magnitude of the slope of the torque curve in the vicinity of the point $s=0$ is the larger, the higher the resistance of the primary or a-c winding, and this explains why the "negative damping" of synchronous machines having a high primary resistance is relatively high.

In figure 8, which relates to the same synchronous machine as figure 6, the curve representing the torque produced by the d-c excitation is given for two different values of the primary resistance. This diagram clearly reveals the effect which the magnitude of the primary resistance has on the slope of the torque curve. In plotting this diagram, the assumption has been made that the electromotive force E is equal to the terminal voltage U.

It should be noted that the d-c excitation will have the effect of lowering the asynchronous torque developed by the machine at the instant at which it pulls into step, for the reason that the torque developed by the d-c excitation has the negative sign.

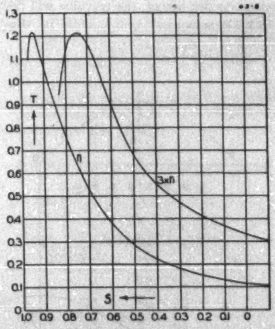

Figure 8. Torque produced by the d-c excitation on the motor, figure 6

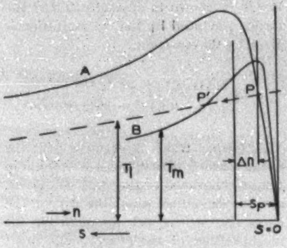

Figure 9. Pulling-into-step conditions

Pulling Into Step

The formula

$$s_p=\frac{621}{n}\sqrt{\frac{N_p}{f\times WR^2}} \tag{10}$$

derived by Edgerton and Zack for the slip at the pull-in point, that is, for the maximum value of the slip at which, under the most unfavorable switching conditions, the machine is still capable of pulling into step, is a very useful one. In fact, this formula has been found to give correct results not only in the case of a synchronized induction motor, but also in the case of a synchronous motor having salient poles. It checks with the formula published by Shoults, Lauder, and Crary in the latest paper devoted to the subject matter in question.

After the machine has reached its highest speed as an induction machine, as given by the torque curve that applies when the field winding of the machine is connected to a resistor (point *P* on curve *A* of figure 9), the d-c energizing voltage is applied to the field winding and the resistor is removed from the circuit. As a consequence hereof, the machine will decelerate somewhat and increase its slip, until it reaches a running point on the new torque curve (point *P'* on curve *B* of figure 9), that is, on the torque curve that is determined jointly by the squirrel-cage effect and by the effect of the d-c excitation. If on this occasion the slip increases to such an extent that it exceeds the value of the slip s_p, the machine will not be capable to pull into step. Tests have proved, however, that it is not necessary to consider the torque curve *B* (resistor removed from the field circuit) as an exclusive criterion of the pull-in conditions. In fact, it can be stated that the machine will pull into step without fail as long as the time interval of deceleration from the speed at point *P* down to the speed corresponding to the value of the slip s_p is of much longer duration than the time constant of the field circuit of the machine (determined for the case that the primary winding is short-circuited). In other words, it is merely necessary to satisfy the condition:

$$\Delta t=\frac{\Delta n}{\frac{T_m}{T_r}-\frac{T_l}{T_r}}\,\frac{WR^2}{307T_r}>T_f \tag{11}$$

Appendix A

The breadth factors ξ_{D_d} and ξ_{D_q} of the two single-axis damper windings can simply be determined by determining the portions of the fluxes B_d and B_q that are linked with the turns of these windings. It has been assumed in figure 10 that the number of cage bars per pole is even, that is, that $q_p=2n$. If, starting from the center line of the pole, the sequence of cage bars located on either side of this axis of symmetry is designated by the natural sequence of digits 1, 2, ... *k*, ... *n*, the resultant coil flux of the direct-axis damper winding per unit core-width of the machine is found to be equal to:

$$\psi=\sum_{k=1}^{k=n}\phi=\sum_{k=1}^{k=n}B_d\int_{\frac{\tau_p-(2k-1)a}{2}}^{\tau_p-\frac{\tau_p-(2k-1)a}{2}}\sin\left(\frac{\pi_p}{\tau}\xi\right)d\xi$$

$$=\frac{2}{\pi}\tau_pB_d\sum_{k=1}^{k=n}\sin\frac{2k-1}{2}\alpha=\frac{2}{\pi}\tau_pB_d\frac{\sin^2\frac{q_p}{4}\alpha}{\sin\frac{\alpha}{2}}$$

while the resultant coil-flux of the quadrature-axis damper winding (figure 6*b*) is found to be equal to:

$$\psi=\sum_{k=1}^{k=n}B_q\int_{-\frac{\tau_p-(2k-1)a}{2}}^{\frac{\tau_p-(2k-1)a}{2}}\cos\left(\frac{\pi}{\tau_p}\xi\right)d\xi$$

$$=\frac{2}{\pi}\tau_pB_q\sum_{k=1}^{k=n}\cos\frac{2k-1}{2}\alpha=\frac{2}{\pi}\tau_pB_q\frac{\sin\frac{q_p}{2}\alpha}{2\sin\frac{\alpha}{2}}$$

The breadth factors of the two windings are then obtained by dividing the expressions just given by $\frac{2}{\pi}\tau_pB_dq_p$ resp. $\frac{2}{\pi}\tau_pB_qq_p$.

If q_p is odd, $q_p=2n+1$, the resultant coil flux of the direct-axis damper winding

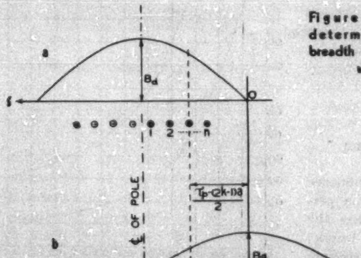

Figure 10. For determination of breadth factors, figures 2 and 3

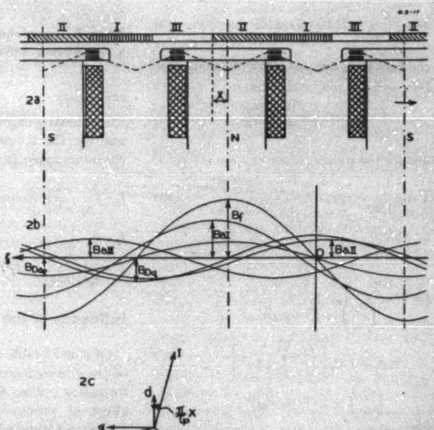

Figure 11. For determination of torque

is found to be equal to:

$$\psi=\frac{2}{\pi}\tau_p B_d\sum_{k=1}^{k=n}\sin(n\alpha)$$

$$=\frac{2}{\pi}\tau_p B_d\frac{\sin\frac{q_p-1}{4}\alpha\sin\frac{q_p+1}{4}\alpha}{\sin\frac{\alpha}{2}}$$

if the bar placed on the center-line of the pole is designated by the numeral zero. In analyzing the quadrature-axis damper winding, the cage bar designated by zero belongs simultaneously to two different winding elements. In view hereof, the resultant coil flux is determined in the first place with the 0th cage bar included in the winding, and in the second place without the 0th cage bar, whereupon the average of the two values thus obtained is computed. The result is:

$$\psi=\frac{1}{2}\frac{2}{\pi}\tau_p B_q\left[\sum_{k=0}^{k=n}\cos(n\alpha)+\sum_{k=1}^{k=n}\cos(n\alpha)\right]$$

$$=\frac{2}{\pi}\tau_p B_q\frac{\sin\frac{q_p}{2}\alpha}{2\sin\frac{\alpha}{2}}$$

The breadth factor of the direct-axis damper winding is obtained in this case by dividing the expression for the resultant coil-flux by $2/\pi\tau_p B_d(q_p-1)$, while the breadth factor of the quadrature-axis damper winding is again obtained by dividing the expression for the resultant coil flux by $2/\pi\tau_p B_q q_p$.

Appendix B

In figure 11*a* are shown the relative positions which the field system and the phase belts of the primary winding of a three-phase synchronous machine have with respect to one another at a given instant t. At this instant, the center of the north pole N is shifted toward the right over a distance x with respect to the center line of the winding phase I. In figure 11*b* are given the three flux-distribution curves for the three winding phases of the primary winding, the flux-distribution curve for the direct-axis damper winding, that for the quadrature-axis damper winding, and that for the field winding. These six fluxes may be replaced in an arbitrary manner by two other fluxes whose axes are perpendicular to each other. We shall choose these two fluxes in such a manner that one of them has its amplitude along the center line of the pole, while the other one has its amplitude along the center line of the interpolar gap; the former flux is then the resultant direct-axis flux B_d, and the latter is the resultant quadrature-axis flux B_q of the machine. It is then readily found (by projection) that the amplitudes B_{I}, B_{II}, B_{III} of the resultant fluxes along the axes of the primary winding phases are expressed by the following formulas (see figure 11*c*):

$$\left.\begin{aligned}B_{\mathrm{I}}&=B_d\cos\frac{\pi}{\tau_p}x-B_q\sin\frac{\pi}{\tau_p}x\\B_{\mathrm{II}}&=-B_d\sin\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)+\\&\qquad B_q\cos\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)\\B_{\mathrm{III}}&=-B_d\sin\left(\frac{\pi}{6}+\frac{\pi}{\tau_p}x\right)-\\&\qquad B_q\cos\left(\frac{\pi}{6}+\frac{\pi}{\tau_p}x\right)\end{aligned}\right\}\quad(12)$$

These amplitudes B_{I}, B_{II}, B_{III} can be expressed in a very simple way in the terminal voltage of the primary if the primary resistance and the primary reactance are neglected. We shall do this in the remaining part of this appendix, and show afterward, in appendix *C*, what the result will be when the primary resistance and the primary reactance are taken into account. But already in this appendix our knowledge of the theory of the induction machine will enable us to predict how r_1 and x_1 will affect the simplified formula that will now be derived.

It follows from the equations by means of which the electromotive forces induced in the primary winding-phases are expressed in the flux pulsations that:

$$\left.\begin{aligned}B_{\mathrm{I}}&=-\frac{\sqrt{2}U}{Z\omega}\cos\omega t\\B_{\mathrm{II}}&=-\frac{\sqrt{2}U}{Z\omega}\cos\left(\omega t-\frac{2\pi}{3}\right)\\B_{\mathrm{III}}&=-\frac{\sqrt{2}U}{Z\omega}\cos\left(\omega t-\frac{4\pi}{3}\right)\end{aligned}\right\}\quad(13)$$

in which

$$Z=\frac{2}{\pi}\tau_p l w_1\,\xi_1\,10^{-8}\quad(14)$$

Upon elimination of B_{I}, B_{II}, B_{III} between (12) and (13), we can solve for B_d and B_q, and obtain:

$$\left.\begin{aligned}B_d&=-\frac{\sqrt{2}U}{Z\omega}\cos\left(\frac{\pi}{\tau_p}x-\omega t\right)\\B_q&=\frac{\sqrt{2}U}{Z\omega}\sin\left(\frac{\pi}{\pi_p}x-\omega t\right)\end{aligned}\right\}\quad(15)$$

But

$$\frac{\pi}{\tau_p}x=\omega_r t$$

and

$$\frac{\pi}{\tau_p}x-\omega t=(\omega_r-\omega)t=-s\omega t\quad(16)$$

so that

$$\left.\begin{aligned}B_d&=-\frac{\sqrt{2}U}{Z\omega}\cos(s\omega t)\\B_q&=-\frac{\sqrt{2}U}{Z\omega}\sin(s\omega t)\end{aligned}\right\}\quad(17)$$

Thereupon we can find the currents in the rotor windings by expressing them in the known fluxes B_d and B_q. In the direct axis of the machine there are two rotor windings, the direct-axis damper winding and the field winding, which are connected in parallel (see figure 4). We shall introduce for this axis the resultant resistance and the resultant reactance, which are given by:

$$r_{2d}=\frac{(r_{Dd}x_{fm}^2+r_f x_{Dm}^2)s^2+r_{Dd}r_f r_{t2}}{r_{t2}^2+s^2x_{t2}^2}\quad(18)$$

$$x_{2d}=\frac{x_{Dd}(r_f^2+s^2x_f^2)+x_f(r_{Dd}^2+s^2x_{Dd}^2)+2x_m(r_{Dd}r_f-s^2x_{Dd}x_f)-s^2x_m^2x_{t2}}{r_{t2}^2+s^2x_{t2}^2}\quad(19)$$

in which:

$$\left.\begin{aligned}x_{Dm}&=x_{Dd}-x_m\qquad &r_{t2}&=r_{Dd}+r_f\\x_{fm}&=x_f-x_m\qquad &x_{t2}&=x_{Dm}+x_{fm}\end{aligned}\right\}\quad(20)$$

x_m designating the reactance corresponding to the mutual inductance due to the leakage fluxes.

The rotor currents for the two axes are then found to be equal to:

$$\left.\begin{aligned}i_{2d}&=-\sqrt{2}U\frac{s}{\sqrt{r_{2d}^2+s^2x_{2d}^2}}\times\\&\qquad\sin\left(s\omega t-tg^{-1}\frac{sx_{2d}}{r_{2d}}\right)\\i_{2q}&=+\sqrt{2}U\frac{s}{\sqrt{r_{Dq}^2+s^2x_{Dq}^2}}\times\\&\qquad\cos\left(s\omega t-tg^{-1}\frac{sx_{Dq}}{r_{Dq}}\right)\end{aligned}\right\}\quad(21)$$

The torque exerted on the stator in the direction opposite to the direction of rotation is equal to (R being the radius of the stator bore):

$$\begin{aligned}T=-2w_1\xi_1 lR\Big[&i_{\mathrm{I}}B_d\cos\left(\frac{\pi}{2}-\frac{\pi}{\tau_p}x\right)-\\&i_{\mathrm{II}}B_d\cos\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)+i_{\mathrm{III}}B_d\cos\left(\frac{\pi}{6}+\frac{\pi}{\tau_p}x\right)+\\&i_{\mathrm{I}}B_q\cos\frac{\pi}{\tau_p}x-i_{\mathrm{II}}B_q\sin\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)-\\&i_{\mathrm{III}}B_q\sin\left(\frac{\pi}{6}+\frac{\pi}{\tau_p}x\right)\Big]\end{aligned}\quad(22)$$

The currents i_{I}, i_{II}, i_{III} appearing in this equation can be expressed in the rotor currents i_{2d} and i_{2q}. This requires, however, that the ampere turns produced by the winding phases of the primary shall be expressed mathematically with reference to a co-ordinate ξ (see figure 7*b*) that rotates together with the rotor. The corresponding expressions are:

$$\left.\begin{aligned}\theta_{\mathrm{I}}&=\Theta_{\mathrm{I}}\sin\left(\frac{\pi}{\tau_p}\xi-\frac{\pi}{\tau_p}x\right)\\\theta_{\mathrm{II}}&=\Theta_{\mathrm{II}}\cos\left(\frac{\pi}{\tau_p}\xi-\frac{\pi}{\tau_p}x+\frac{\pi}{6}\right)\\\theta_{\mathrm{III}}&=-\Theta_{\mathrm{III}}\sin\left(\frac{\pi}{\tau_p}\xi-\frac{\pi}{\tau_p}x+\frac{\pi}{3}\right)\end{aligned}\right\}\quad(23)$$

and apply for any value of the time t, while the resultant magnitude of all the primary ampere-turns is equal to:

$$\Theta_{\mathrm{I}}+\Theta_{\mathrm{II}}+\Theta_{\mathrm{III}}=\Theta_{1d}\sin\frac{\pi}{\tau_p}\xi+\Theta_{1q}\cos\frac{\pi}{\tau_p}\xi\quad(24)$$

in which:

$$\left.\begin{aligned}\Theta_{1d}&=\theta_{\mathrm{I}}\cos\frac{\pi}{\tau_p}x-\Theta_{\mathrm{II}}\sin\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)-\\&\qquad\Theta_{\mathrm{III}}\cos\left(\frac{\pi}{3}-\frac{\pi}{\tau_p}x\right)\\\Theta_{1q}&=-\Theta_{\mathrm{I}}\sin\frac{\pi}{\tau_p}x+\Theta_{\mathrm{II}}\cos\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)-\\&\qquad\Theta_{\mathrm{III}}\sin\left(\frac{\pi}{3}-\frac{\pi}{\tau_p}x\right)\end{aligned}\right\}\quad(25)$$

Equation 25 indicates how the three primary ampere-turn distributions can be replaced by two ampere-turn distributions that rotate together with the rotor, one of the latter ampere-turn distributions having its amplitude (Θ_{1d}) on the center line of the pole, while the other one has its amplitude (Θ_{1q}) on the center line of the interpolar gap. The ampere-turn distribution with amplitude Θ_{1d} is the direct axis, and the one with amplitude Θ_{1q} is the quadrature-axis distribution produced by the primary winding.

It then follows that the resultant direct-axis distribution is equal to:

$$\Theta_d=\Theta_{1d}+\Theta_{2d} \tag{26}$$

while the resultant quadrature-axis distribution is equal to:

$$\Theta_q=\Theta_{1q}+\Theta_{2q} \tag{27}$$

These equations give, in connection with (25), for the amplitude of the resultant direct-axis flux:

$$B_d=c_d\left[i_{\mathrm{I}}\cos\frac{\pi}{\tau_p}x-i_{\mathrm{II}}\sin\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)-i_{\mathrm{III}}\cos\left(\frac{\pi}{3}-\frac{\pi}{\tau_p}x\right)\right]+c_di_{2d} \tag{28}$$

and for the amplitude of the resultant quadrature-axis flux:

$$B_q=c_q\left[-i_{\mathrm{I}}\sin\frac{\pi}{\tau_p}x+i_{\mathrm{II}}\cos\left(\frac{\pi}{6}-\frac{\pi}{\tau_p}x\right)-i_{\mathrm{III}}\sin\left(\frac{\pi}{3}-\frac{\pi}{\tau_p}x\right)\right]+c_qi_{2q} \tag{29}$$

When the expressions for B_d and B_q given by (28) and (29) are introduced into the torque equation 22, this equation becomes:

$$T=Zp\left(i_{2d}B_q-i_{2q}B_d+\frac{c_d-c_q}{c_dc_q}B_dB_q\right) \tag{30}$$

and if subsequently the values for B_d and B_q as given by (17) and the values for i_{2d} and i_{2q} as given by (21) are introduced into (30), the equation expressing the starting torque as a per-unit quantity is obtained in the form:

$$T=\frac{1}{2}\left[\frac{r_{2d}}{\left(\frac{r_{2d}}{s}\right)^2+x_{2d}^2}+\frac{r_{Dq}}{\left(\frac{r_{Dq}}{s}\right)^2+x_{Dq}^2}-\frac{1}{\sqrt{\left(\frac{r_{2d}}{s}\right)^2+x_{2d}^2}}\cos\left(2s\omega t-t_g^{-1}\frac{sx_{2d}}{r_{2d}}\right)+\frac{1}{\sqrt{\left(\frac{r_{Dq}}{s}\right)^2+x_{Dq}^2}}\cos\left(2s\omega t-t_g^{-1}\frac{sx_{Dq}}{r_{Dq}}\right)-\frac{c_d-c_q}{c_dc_q}\frac{1}{\omega Z}\sin(2s\omega t)\right] \tag{31}$$

The first two terms of the expression between square brackets appearing in the second member of this equation represent the constant torque components produced respectively by the direct-axis damper winding and by the quadrature-axis damper winding. The third, fourth, and fifth terms represent torque components that pulsate with twice the slip frequency, the third and the fourth terms being due to the unsymmetry of the damper winding, and the fifth term to the difference in the values of the magnetic reluctance in the direct axis and in the quadrature axis.

On the basis of our knowledge of the theory of induction machines, we can indicate at once the more general form which the constant component of the torque will have when the primary resistance and the primary reactance of the machine are taken into account:

$$T=\frac{1}{2}\left[\frac{\frac{r_{2d}}{s}}{\left[r_1+(1+\tau_{1d})\frac{r_{2d}}{s}\right]^2+[x_1+(1+\tau_{1d})x_{2d}]^2}+\frac{\frac{r_{Dq}}{s}}{\left[r_1+(1+\tau_{1q})\frac{r_{Dq}}{s}\right]^2+[x_1+(1+\tau_{1q})x_{Dq}]^2}\right]$$

Appendix C

An investigation of the influence of the d-c excitation and of the primary resistance and reactance on the starting performance will not be dependent on the manner in which the rotor windings are arranged on the field system. In other words, we are free to assume that the machine has no damper winding, its field system being equipped only with a magnetizing winding. The investigation can further be simplified by assuming that the stator of the machine is equipped with a two-phase winding. The set of equations 12 must then be replaced by the set:

$$\left.\begin{aligned}B_{\mathrm{I}}&=B_d\cos\frac{\pi}{\tau_p}x-B_q\sin\frac{\pi}{\tau_p}x\\B_{\mathrm{II}}&=B_d\sin\frac{\pi}{\tau_p}x+B_q\cos\frac{\pi}{\tau_p}x\end{aligned}\right\} \tag{32}$$

and the voltage equations for the three circuits appear in the form:

$$\left.\begin{aligned}\sqrt{2}u\sin\omega t&=Z\frac{dB_{\mathrm{I}}}{dt}+L_1\frac{di_{\mathrm{I}}}{dt}+r_1i_{\mathrm{I}}\\\sqrt{2}u\cos\omega t&=Z\frac{dB_{\mathrm{II}}}{dt}+L_1\frac{di_{\mathrm{II}}}{dt}+r_1i_{\mathrm{II}}\\U_f&=Z\frac{dB_d}{dt}+L_f\frac{di_f}{dt}+r_fi_f\end{aligned}\right\} \tag{33}$$

The torque equation 30 can be written in this case more simply:

$$T=Zp\left[i_fB_q+\frac{c_d-c_q}{c_dc_q}B_dB_q\right] \tag{34}$$

The quantities i_f, B_q, and B_d appearing in the latter equation have to be expressed in the voltages applied to the windings of the machine. This requires in the first place that in the voltage equations 33 the quantities B_{I}, B_{II}, i_{I}, i_{II} shall be replaced by B_d, B_q, and i_f. Equation 32 gives us one relation, between B_{I}, B_{II} on the one hand and B_d, B_q on the other hand. Additional relations are obtained by writing down equations analogous to (28) and (29) for the case under consideration:

$$B_d=c_d\left(i_f+i_{\mathrm{I}}\cos\frac{\pi}{\tau_p}x+i_{\mathrm{II}}\sin\frac{\pi}{\tau_p}x\right) \tag{35}$$

$$B_q=c_q\left(-i_{\mathrm{I}}\sin\frac{\pi}{\tau_p}x+i_{\mathrm{II}}\cos\frac{\pi}{\tau_p}x\right) \tag{36}$$

If we now introduce a new variable, defined by:

$$I_d=\frac{B_d}{c_d}-i_f \tag{37}$$

we can bring the equations 35 and 36 into the following form:

$$\left.\begin{aligned}i_{\mathrm{I}}&=I_d\cos\frac{\pi}{\tau_p}x-\frac{B_q}{c_q}\sin\frac{\pi}{\tau_p}x\\i_{\mathrm{II}}&=I_d\sin\frac{\pi}{\tau_p}x+\frac{B_q}{c_q}\cos\frac{\pi}{\tau_p}x\end{aligned}\right\} \tag{38}$$

We can now substitute in the voltage equations 33 for B_{I} and B_{II} the values given by (32), and for i_{I} and i_{II} the values given by (38), whereupon, with the aid of the relations expressed by (16) and of those given in the following:

$$Zc_d=\frac{x_{ad}}{\omega}\qquad Zc_q=\frac{x_{aq}}{\omega}$$

$$\frac{L_1}{Zc_d}=\tau_{1d}\qquad\frac{L_1}{Zc_q}=\tau_{1q}\qquad\frac{L_f}{Zc_d}=\tau_2$$

$$1+\tau_{1d}=k_{1d}\qquad1+\tau_{1q}=k_{1q}\qquad1+\tau_2=k_2$$

the voltage equations can be brought into the form:

$$\left.\begin{aligned}-Z\omega_rB_d-\frac{r_1}{c_q}B_q-L_1\omega_rI_d-Zk_{1q}B_q'&=\sqrt{2}U\cos(s\omega t)\\-Z\omega_rk_{1q}B_q+r_1I_d+ZB_d'+L_1I_d'&=\sqrt{2}U\sin(s\omega t)\\\frac{r_f}{c_d}B_d-r_fI_d+Zk_2B_d'-L_fI_d'&=U_f\end{aligned}\right\} \tag{39}$$

The latter equations immediately give us three linear, nonhomogeneous differential equations of the third order, which, upon solution, yield the following expressions for the three unknown variables:

$$\left.\begin{aligned}B_d&=\frac{C_dG+D_dH}{G^2+H^2}\sin(s\omega t)+\frac{D_dG-C_dH}{G^2+H^2}\cos(s\omega t)+\frac{K_d}{a_8}\\B_q&=\frac{C_qG+D_qH}{G^2+H^2}\sin(s\omega t)+\frac{D_qG-C_qH}{G^2+H^2}\cos(s\omega t)+\frac{K_q}{a_8}\\I_d&=\frac{C_IG+D_IH}{G^2+H^2}\sin(s\omega t)+\frac{D_IG-C_IH}{G^2+H^2}\cos(s\omega t)+\frac{K_I}{a_8}\end{aligned}\right\} \tag{40}$$

in which:

$$K_d=\frac{U_f}{Z}\left[\frac{r_1^2}{Zc_q}+\omega_r^2k_{1q}L_1\right]$$

$$C_d=-\frac{\sqrt{2}U}{Z}k_{1q}s\omega L_f\left[\omega(2s-1)-\frac{r_1r_f}{Zc_qk_{1q}s\omega L_f}\right]$$

$$D_d=\frac{\sqrt{2}U}{Z}k_{1q}r_f\left[\omega(2s-1)+\frac{r_1s\omega L_f}{Zc_qk_{1q}r_f}\right]$$

$$K_q=-\frac{U_f}{Z}r_1\omega_r$$

$$C_q=\frac{\sqrt{2}U}{Z}k_{1d}r_f\left[\omega(2s-1)+\frac{s\omega r_1k_2}{r_fk_{1d}}\right]$$

$$D_q=\frac{\sqrt{2}U}{Z}s\omega(L_fk_{1d}+L_1)\left[\omega(2s-1)-\frac{r_1r_f}{Zc_ds\omega(L_fk_{1d}+L_1)}\right]$$

$$K_1=-\frac{U_f}{Z}\omega_r^2k_{1q}^2$$

$$C_1=-\frac{\sqrt{2}U}{Z}\,s\omega Zk_2k_{1q}\left[\omega(2s-1)-\frac{r_1r_f}{Zc_dZc_qk_2k_{1q}s\omega}\right]$$

$$D_1=\frac{\sqrt{2}U}{Z}k_{1q}\frac{r_f}{c_d}\left[\omega(2s-1)+\frac{r_1s\omega k_2Zc_d}{r_fZc_qk_{1q}}\right]$$

$$G=a_3-(s\omega)^2a_1$$
$$H=-s\omega[a_2-(s\omega)^2a_0]$$

$$a_1=\frac{r_1}{Zc_q}(L_fk_{1d}+L_1)+k_{1q}(r_fk_{1d}+r_1k_2)$$

$$a_2=\frac{r_1r_f}{Zc_d}k_{1q}+\frac{r_1}{Zc_q}(r_fk_{1d}+r_1k_2)+\omega_r^2k_{1q}(L_fk_{1d}+L_1)$$

$$a_3=r_f\left(\frac{r_1^2}{Zc_dZc_q}+\omega_r^2k_{1d}k_{1q}\right)$$

$$a_0=k_{1q}(L_fk_{1d}+L_1)$$

Since the torque equation 34 can be brought into the form:

$$T=ZpB_q\left[\frac{B_d}{c_q}-I_d\right] \tag{41}$$

the torque can be readily calculated with the aid of the equations 40. As in appendix *B*, the torque obtained in this case consists of components of constant magnitude and of components that vary with time. In order to obtain for the torque an expression which clearly reveals these various components, we first simplify the derivation by introducing into the set of equations 40:

$$\left.\begin{aligned}B_q&=\lambda_{1Q}\sin(s\omega t)+\lambda_{2Q}\cos(s\omega t)+\lambda_{3Q}\\ \frac{B_d}{c_q}-I_d&=\lambda_{1D}\sin(s\omega t)+\lambda_{2D}\cos(s\omega t)+\lambda_{3D}\end{aligned}\right\}\tag{42}$$

The expression for the torque can then be written:

$$T=\text{const.}\left\{\frac{\lambda_{1Q}\lambda_{1D}+\lambda_{2Q}\lambda_{2D}}{2}+\left[\frac{\lambda_{2Q}\lambda_{2D}-\lambda_{1Q}\lambda_{1D}}{2}\cos(2s\omega t)+\frac{\lambda_{1Q}\lambda_{2D}+\lambda_{2Q}\lambda_{1D}}{2}\sin(2s\omega t)\right]+[(\lambda_{1Q}\lambda_{3D}+\lambda_{1D}\lambda_{3Q})\sin(s\omega t)+(\lambda_{2Q}\lambda_{3D}+\lambda_{2D}\lambda_{3Q})\times\cos(s\omega t)]+\lambda_{3Q}\lambda_{3D}\right\} \tag{43}$$

The pulsating torque components are produced by the same causes as in appendix *B*. The constant torque components are two in number. The first component

$$\text{const.}\frac{\lambda_{1D}\lambda_{1Q}+\lambda_{2D}\lambda_{2Q}}{2}$$

is produced by the effect of the primary or stator flux on the field winding (which plays in this respect the role of a secondary or induced winding) and actually constitutes the "asynchronous" torque delivered by the machine. This torque component is only of interest to us in the present case in so far as we expect it to reveal the effect which the primary resistance and the primary reactance have on the torque. A complete analysis shows that the primary reactance enters into the equation as an additive term in conjunction with the secondary reactance. The influence of the primary resistance is not as simple as in the case in which equation 4 applies, as a consequence of the fact that the rotor winding of the machine is now a single-axis winding. If it is assumed that $c_d=c_q$, the following quantity appears in numerator of the expression for the torque:

$$\omega(2s-1)Z\left[\omega(2s-1)k_{1d}+\frac{r_1}{r_f}\frac{s\omega}{k_{1d}}\right]$$

and it is seen that this quantity becomes zero for $s=0.5$, making the torque equal to zero at a running speed in the vicinity of one-half the synchronous speed. This is nothing but the well-known phenomenon encountered in the operation of a polyphase induction motor having a single-phase rotor winding. This vanishing of the torque will not occur, however, in the limiting case where $r_1=0$. And this peculiar influence of r_1 on the torque curve will hardly be noticeable when the field system is equipped with a damper winding.

The primary resistance r_1 further affects the second constant component of the torque, the component represented by const. $\lambda_{3Q}\lambda_{3D}$. This torque component is produced by the field current in conjunction with the currents in the primary winding; its magnitude is given by equation 9. It has been shown in the foregoing that this torque component is negative during the entire starting period, that is, from standstill up to synchronism, and that for this reason the starting process may be adversely affected when d-c excitation is applied too soon to the field winding. This torque component has normally its maximum in the neighborhood of the standstill point.

List of Symbols

a = distance between two rotor bars
B_d = field amplitude in the direct axis
B_q = field amplitude in the quadrature axis
c_d = constant given by equation 28, appendix *B*
c_q = constant given by equation 29, appendix *B*
E = electromotive force induced in the stator winding by the rotor flux
f = line frequency
I_f = forward current
I_b = backward current
$K_{1d}=1+\tau_{1d}$
$K_{1q}=1+\tau_{1q}$
l = ideal core width
$L=\frac{x_1}{2\pi f}$ coefficient of the primary leakage inductance
m_1 = phase number of the primary winding
n = revolutions per minute
p = number of pole pairs
q_p = number of damper bars per pole
r_1 = primary resistance
r_f = resistance of the field circuit
r_{Dd} = resistance of the direct-axis damper winding
r_{Dq} = resistance of the quadrature-axis damper winding
r_{2d} = resultant secondary resistance in the direct axis
T = torque
T_f = time constant of the field circuit
U = terminal voltage of the stator
w_1 = number of turns of the primary winding per phase
x_1 = primary leakage reactance
x_f = leakage reactance of the field winding
x_{Dd} = leakage reactance of the direct-axis damper winding
x_{Dq} = leakage reactance of the quadrature-axis damper winding
x_m = mutual-inductance reactance due to the leakage fluxes of direct-axis damper winding and field winding
x_{2d} = resultant secondary leakage in the direct axis
x_{ad} = reactance due to the main flux in the direct axis
x_{aq} = reactance due to the main flux in the quadrature axis
$x_d=x_1+x_{ad}$
$x_q=x_1+x_{aq}$
α = angle between two damper bars
η = efficiency
θ = magnetomotive force
Θ = amplitude of the magnetomotive force distribution
ξ_1 = distribution factor times chord factor of the primary winding
ξ_{Dd} = breadth factor of the direct-axis damper winding
ξ_{Dq} = breadth factor of the quadrature-axis damper winding
$\omega=2\pi f$
$\omega_r=\frac{2\pi pn}{60}$
τ_p = pole pitch
$\tau_{1d}=\frac{x_1}{x_{ad}},\ \tau_{2d}=\frac{x_{2d}}{x_{ad}},\ \tau_{1q}=\frac{x_1}{x_{aq}},\ \tau_{2q}=\frac{x_{Dq}}{x_{aq}}$

Heating of a D-C Armature

CARL J. FECHHEIMER
FELLOW AIEE

I. Purposes

THE purposes of these investigations were: (1) to determine what the maximum temperatures of the copper and iron were, and to compare those maximum temperatures with thermometer readings; (2) to measure the average of the maximum temperatures by resistance and to compare the results with the average secured from the maximum copper temperatures; (3) to measure the surface temperatures by means of a special contact thermocouple, and to compare those readings with those obtained by other means; (4) to measure the maximum commutator temperatures in several axial positions by the contact thermocouple, and to compare the results with thermometer readings; (5) to determine more accurate methods of calculating temperatures; and (6) to determine how to decrease the temperatures.

II. Special Measurements and Methods of Conducting Tests

The tests were made on a 300-kw 1,200-rpm 250-volt armature, the d-c machine being direct connected to a synchronous motor. When the motor generator set was disconnected from the line, dynamic braking was used on the synchronous machine, so that the set was brought to a standstill in very short time, and readings were taken before there was sufficient internal heat flow to modify the maximum temperatures greatly. The maximum temperatures were obtained by plotting temperature-time curves on semi-log paper projected back to the instant of shutdown.

The tests were made several years ago on a machine that was recognized to be unsatisfactory from the standpoint of heating, and the design has since been modified. It is believed that some of the methods of measurement used were novel, and that descriptions of similar methods have not appeared in the technical press.

DESCRIPTION OF APPARATUS

It is recognized that temperature measurements of the bare copper, or of the iron in a rotating armature by detectors are generally unsatisfactory, because when slip rings are used, too many rings are required if a large number of readings is desired, and if thermocouples are employed, there are liable to be inaccuracies. The method adopted was to use thermocouples, and to take a series of readings, which when plotted against time and extrapolated back to zero time, gave the maximum temperatures.

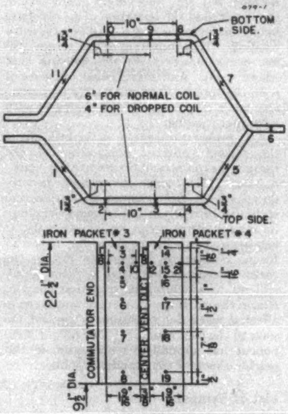

Figure 1. Location of embedded thermocouples

The thermocouple junctions on the bare copper were formed by soldering number 26 constantan wire to the copper conductor (the armature copper being the copper side of the junctions), there being a total of 11 junctions on each of two adjacent armature coils, located as shown in figure 1. One of the armature coils was of the usual type; the other was dropped at the rear for suitable cross connectors. They are designated as "normal" and "dropped" coils. It was necessary to have only one copper wire lead from the armature copper to serve for all 22 thermocouples on the armature copper. The constantan leads were all brought out at the rear at the U bends of the coils.

In two iron packets axially adjacent to the central vent duct, thermocouple junctions were placed, arranged as shown in figure 1. The iron packets selected were circumferentially between the top sides of the two adjacent coils referred to above. The thermocouple metals used were 0.005 inch thick, copper and constantan, and were insulated with mica from the iron. Near the inner periphery, a few laminations were cut back $\frac{1}{2}$ inch; number 26 copper and constantan wires were soldered on, and the wires were brought out axially through a slot cut in one of the spider arms to the rear of the armature. Suitable sleeving was placed over the wires in the slot.

In order to secure readings rapidly after shutdown, three special plug boards were made, each provided with 15 contacts. The construction is shown in figures 2 and 3, and photographs (figures 4 and 5) show the plug boards on the machine. The three boards were spaced 120 degrees apart, and each board was provided with guide pins so that they could be pushed "home" after shutdown without loss of time. In each of the individual contacts, the stationary member had a projecting

Paper 40-79, recommended by the AIEE committee on electrical machinery, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted October 17, 1939; made available for preprinting January 3, 1940; released for final publication March 8, 1940.

CARL J. FECHHEIMER is consulting engineer, Milwaukee, Wis.

1. For all numbered references, see list at end of paper.

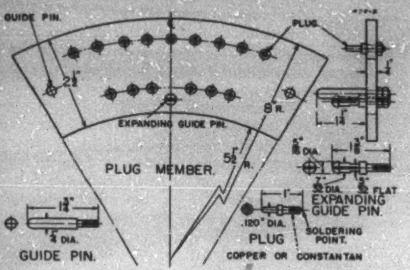

Figure 3. Plug side of plug board

pin which fitted loosely into the hole bored into its mate in the revolving member. The contact was made at the shoulder, suitable springs being provided to insure ample pressure at that surface. The precaution was observed of making the two members of each plug of the same kind of metal as the lead-in and lead-out wires; otherwise there might have been a difference in temperature which would have introduced an error. Each wire leading from the stationary parts of the plugs was joined to a contact button on a dial plate, there being two dial plates in use simultaneously. Readings were taken with potentiometers.

Two men took observations at each dial plate. As soon as the main circuits were opened, one man started a stop watch, and the other started to take readings as soon as the machine was stopped, turned over to the proper position, and the plug boards joined to the receptacle members. From five to seven thermocouples were read on each dial plate in succession, the time and potentiometer reading recorded by the man with the stop watch. After reading the series, they were successively repeated for a total lapse of about 15 minutes. It was possible to obtain an initial reading in about 45 seconds after the main circuits were opened. The temperature test was repeated until all thermocouples were read.

Figure 4. Receptacle and plug members disconnected

The average temperature was obtained by measuring a part of the armature resistance. The positions for measurement were marked on the commutator, the measurement being made on less than the span of one pole, so as not to include the effect of short-circuiting by the brushes. The particular coils in which the thermocouples were placed were included in the group measured. The armature was turned after shutdown so as to occupy the same position as when the cold resistance was measured. The cold resistance was measured at intervals during about six hours, the armature temperature by thermometer being noted during that period of time. All resistances were measured with the same Kelvin bridge.

Figure 5. Receptacle and plug members connected

A special contact thermocouple was also made in which a very thin ribbon junction was laid on cork placed in a recess near the end of a Micarta bar of square cross section. See figures 6 and 7. The cork acted as a spring when the thermocouple junction was pressed against the surface. The cork has low specific thermal capacity, and is a very poor conductor of heat, which made for quick response and accuracy. The contact thermocouple was used for securing iron surface and commutator temperatures. Time readings were taken along with the other readings.

Thermometer readings were taken in the usual manner, and time readings were taken. In this way, a comparison is made between the maximum temperatures and thermometer readings, at the instant that the thermometers reached their maxima, as well as the maxima noted by other means prior to the thermometers reading their maxima.

III. Results

In figure 8, the important parts of the armature are shown.

Only a few of the test time-temperature curves are included. The end points were obtained by plotting on semi-log paper, and although those curves were not quite straight lines, greater accuracy was obtained that way than by projecting back on usual co-ordinate paper.* The curves included herewith are all plotted on usual paper, they having been transcribed from the semi-log plots.

Figures 9 and 10 are typical bare-copper time-temperature curves of various positions on one of the "dropped" coils at 100 per cent load. Figure 9 is for the top, and figure 10 for the bottom side of the same coil. A similar set of curves, but for the iron and for 125 per cent load, for various radial positions, are shown in figure 11. A comparison between contact thermocouple and thermometer readings can be obtained from figure 12. Another typical set of thermometer time-temperature curves is given in figure 13. An armature time-resistance curve is shown in figure 14.

The distribution of initial (end point) temperatures radially in the iron for the various conditions of load is shown in figure 15. In all except the no-load tem-

Figure 7. Contact thermocouple

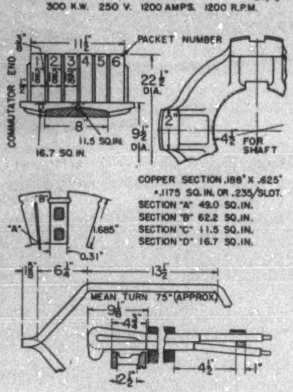

Figure 8. Drawing of parts

perature test (for which they were substantially equal), the temperatures in packet number 3 (near the commutator end) were higher than in packet number 4. This is because the air flow was restricted by the limited section between the internal periphery of the core and the external periphery of the spider hub (see figure 8). With load, the temperatures in packet number 3 were appreciably higher than in number 4. In figure 16 the axial distribution in the iron is shown for 125 per cent load. The axial temperature distribution in an iron packet should theoretically be a parabola with its maximum at or near the middle of the packet; however for packet number 4 the maximum was near the central vent duct, proving that there was insufficient air passing through that vent. The temperature near the central vent for packet number 3 is not far from that in number 4, but it rises toward the middle of the packet, and its average is greater than for number 4. Unfortunately, the thermocouple nearest to the commutator side in packet number 3 open-circuited, so that the complete axial distribution curve in that packet could not be obtained.

Some commutator temperature rises are plotted in figure 17. They are from two tests at 100 per cent load by thermometer, one at 125 per cent load by thermometer and by contact thermocouple, and one at 125 per cent current on short-circuit by contact thermocouple. The results are interesting, because they show how much lower the readings by thermometer were than by contact thermocouple, and because they show the approximate axial distribution of temperatures. In figure 18, time-temperature tests for 125 per cent load by contact thermocouple and thermometer are plotted. It is of interest to note that for such time as was required for the thermometer to reach its maximum, the reading was only a few degrees lower by thermometer than by contact thermocouple, but the end-point temperature by the latter was considerably higher than by the former method.

The maximum test temperatures are recorded in table I, data being given therein as can be read from the curves, but as only a few representative curve sheets are included in this paper, some data in table I cannot be obtained from the curve sheets.

In figure 19 are shown the test and calculated longitudinal temperature distribution along the copper at 100 per cent load. The curves are for the top and bottom coils, and the test points apply to the normal and to the dropped coil. The test points are the maxima, or end points. The calculated curves are symmetrical about the center line, but the test curves are not. This is because, as previously mentioned, the air flow was restricted by the limited section between the inner periphery of the core and the external periphery of the spider hub. Especially did this apply for the location at the central vent, and consequently the embedded copper temperatures were higher at the side nearer to the commutator than those nearer to the rear. The agreement between test and calculation for the top coil is quite close, but there are appreciable differences for the bottom coil: the test temperatures were higher than calculated. This may be explained by the following: (1) there probably was more heat flow from the top to the bottom coils than was allowed for in the calculations; (2) due to higher magnetic densities, the tooth loss adjacent to the bottom coil was considerably higher than for the top part; (3) and that there was some eddy current loss in the bottom coil due to flux threading it because of tooth saturation, an allowance having been made, but was probably insufficient. An interesting point is that the maximum temperature

Figure 9. Bare copper time-temperature curves

Top side of coil, "dropped" coil

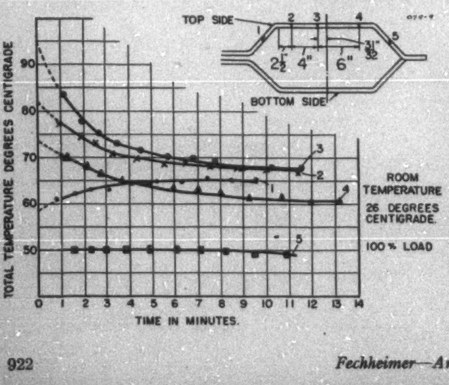

Figure 10. Bare-copper time-temperature curves

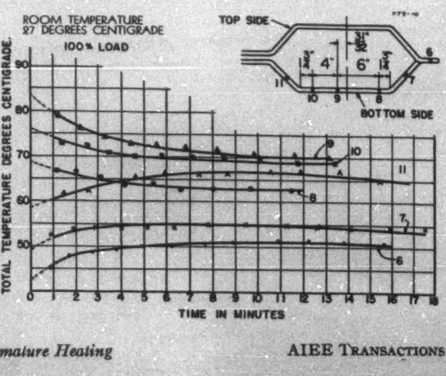
Bottom side of coil, "dropped" coil



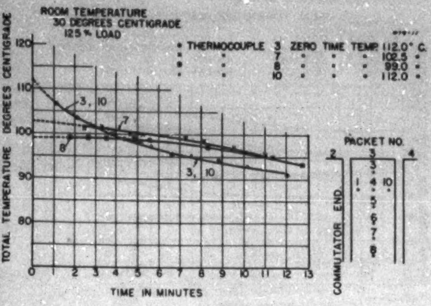


Figure 11. Iron-packet time-temperature curves by embedded thermocouple

at, or near, the center line would be considerably higher were the influence of longitudinal flow in the copper absent. The calculations indicate that it would have been about 16 degrees higher at 100 per cent load, and about 26 degrees higher at 125 per cent load. In longer-core machines the beneficial effect of longitudinal flow would not have been so effective in reducing the copper temperatures.

Without doubt, the considerable difference between the top and bottom coil temperatures is due to the difference in eddy-current loss. By stranding the copper, as has been done in subsequent machines, this loss is greatly reduced.

The curves in figure 19 were calculated by the methods given by Soderberg[1] and the writer.[2] The calculations are long and tedious, and few engineers can find sufficient time for such laborious calculations. Those calculations, therefore, are not included in this paper. A method which appears in another paper,[3] is therefore suggested. That would involve tests on a number of armatures, and from such tests constants can be obtained, from which temperatures in other armatures of comparable proportions can be predicted. A few results of such application to the particular armature tested are given subsequently by way of illustration; such tests, if conducted with care, particularly in regard to the measurement of temperature, should not be expensive.

IV. Comments Upon Results

In order that a clearer mental picture of the temperatures be obtained, more important maximum temperature rises are given in table II.

Although the particular armature on which these investigations were conducted is probably not typical of most d-c armatures, and the differences in temperatures between the various methods of measurement were consequently greater than they would be in most armatures, it will be evident that the usual method of measurement by thermometer does not give the maximum temperature. Thus, the iron rise at normal load was 39 degrees by thermometer, 48 degrees by contact thermocouple, and 71 degrees by embedded thermocouple. Whereas embedded detectors can be employed only in occasional machines, the contact thermocouple can be used readily, is inexpensive, and gives more reliable readings than does a thermometer. Also, the temperature rises of the commutator were appreciably higher by contact thermocouple than by thermometer; and although the armature was not of modern design, which was partly the cause of large differences between embedded and surface measurements, this does not apply to the commutator. The writer has used a contact thermocouple frequently on other machines since these tests were made, and has come to the belief that it is a dependable method for measuring surface temperatures.

The peculiar shape of the contact-thermocouple curve in figure 12 is interesting. The initial rise is readily explained by the thermal capacity of the measuring device. An explanation for the second rise is that the heat flow from the copper to the iron was sufficient to more than counterbalance heat escapement from the external surface. The second maximum was reached at 12.5 minutes; and by comparison with figures 9 and 10, the mean of the top and bottom coil copper near the middle of the armature was about 3.5 degrees higher than the iron by contact thermocouple at the instant, which is a reasonable difference.

Attention is called to average temperature rises. In tables II and III they are given as (1) by resistance, (2) by mean of ordinates of initial temperatures (from figure 19 for 100 per cent load and similar curves, not included with this paper, for 125 per cent load). The calculated average temperature rises in table III were obtained by the method given in two previous papers.[1,2]

V. Calculations From Tests

In table III will be found in parallel columns calculations of temperature rise and test results. The calculations are from no-load and short-circuit tests, as described in a previous paper.[3] For the test results, the averages for the bare copper were taken as the arithmetical mean for location numbers 3 and 9 (see figure 1), for both normal and dropped coils. The averages for the iron by embedded thermocouples are the mean of readings at 100 per cent load at positions 3, 4, 5, 14, 15, and 16; and at 125 per cent load the mean for positions 3, 14, 15, and 16. For all thermocouple readings in table III, the extreme values entering into the determination of the averages are also recorded. For all thermocouple readings in table III, the extreme values entering into the determination of the averages are also recorded in table III.

For calculating the detector temperature rises in table III, the means for the

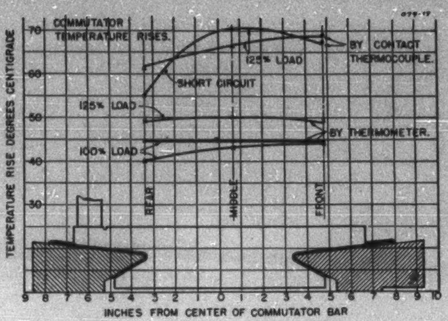

Figure 17. Maximum temperature rise distribution on commutator

copper and iron temperature rises from the no-load and short-circuit tests, for positions as mentioned above, were used for determining the heat resistance factors, R_{11}, R_{12}, and R_{22}, as given in the previous paper.[3] Suitable allowances were made for air rise, θ_{a1} for both heat runs. The load temperature rises were then calculated by equations 20 and 22 in the same paper.[3] Considering the rather wide variation in load test readings, it is believed that the calculated temperature rises check reasonably well with those from test.

The calculated temperature rises by thermometer in table III were obtained by adding the maximum thermometer rises from the no-load and short-circuit temperature tests, without correction for the increase in losses due to incremental increases of copper temperature. The justification for neglecting departures in air temperature is that the tests on open circuit and short circuit were for the same voltage and current for load conditions as obtained in the 125 per cent load test; the sum of the air temperature rises for the two cases is substantially the same as the temperature rise of the air with the same load, since the sum of the losses for the two tests is nearly the same as for 125 per cent load. There would be a slight correction downward for the 100 per cent load test, and had this been done the agreement would probably have been better. The use of the maximum readings from the no-load and short-circuit tests compensates in part for not having allowed for the increase in copper resistance with temperature.

For the contact-thermocouple readings, the readings are all for packet number 4, as the readings for packet number 3 were incomplete. Allowances for increased copper resistance were made on the basis of the sum of the constituent temperature rises.

VI. Conclusions

1. The internal temperatures of a rotating armature can be measured with what is believed to be considerable accuracy with embedded thermocouples and by taking series of time-temperature readings, if care and precautions are observed. The points should be plotted on semi-log paper and projected back to zero time.

2. Surface temperatures of the armature iron, coil ends, and commutator can be measured quicker with a contact thermocouple than with thermometers. It is believed, also, that the results are more accurate with the former than with the latter method, and generally show higher temperatures.

3. Armature average temperature rise by resistance can be measured with considerable accuracy if (*a*) the hot and cold measurements are made between the same commutator bars which do not include any brushes; (*b*) a series of time-temperature readings is taken and plotted on semi-log paper; (*c*) the

same instrument, preferably a Kelvin bridge, is used for the hot and cold readings; and (*d*) cold readings of resistance are taken over a sufficiently long period to insure that the temperature of the armature copper is the same as that of the armature surface, measured by thermometer, or other suitable means.

4. The commutator surface temperatures may be appreciably higher than determined by the usual thermometer method. It is believed that an improvement can be effected with the aid of a contact thermocouple.

5. A suggested method for predicting temperatures is to make open and short-circuit tests on typical machines, and obtain data for typical slotting, from which heat resistance factors can be obtained for future calculations. For securing such data, it may be advisable that the armature be run at no load at a number of speeds and excitations, and on short circuit at perhaps two values of current.

6. General conclusions as to temperature differences between actual copper (or iron) and thermometer (or contact thermocouple) cannot be drawn from tests on a single armature. It is believed that the methods may prove to be helpful to others working in the same, or similar fields.

7. For the particular armature that was used in these investigations, reductions in temperatures could be secured by (*a*) stranding the conductors, so as to reduce the eddy current loss, and (*b*) increasing the section for axial air flow by changing the mechanical design of the spider hub. The particular armature tested has been obsolete for a number of years, and these suggestions have been adopted in more recent machines. Mica insulation has been used for a great many years, and this was especially the case for armatures of older design, thereby safeguarding them against failure.

"Excitron" Mercury-Arc Rectifiers

O. K. MARTI
FELLOW AIEE

FOR some time it was hoped that the present active research in atomic nuclear physics would solve many of the unknown phenomena connected with the electric arc, especially the arc in vacuum, and that this would clarify some of the phenomena of the rectification process in a vacuum tube. However, in spite of the fact that little progress was made in applying the latest theories to the practical application of rectifiers, nevertheless, a considerable step forward was made during the last few years in the design of large electronic glass and metal tubes.

The conventional rectifiers of the multiple-anode type have been perfected during the last decade to such an extent that extremely satisfactory service can be given for any kind of power load. However, they have one drawback, and that is the fact that the arc drop increases with the increase in size of the rectifier tank or tube. It can easily be seen in figure 1 that by increasing the tank diameter D, and therefore the distance of the anodes from the cathode, consequently this increases the arc length, a, which results in higher arc-drop loss and lower efficiency. The arc length could be reduced by providing a cathode pool of very large diameter or a ring cathode. This, however, would complicate the design of the rectifier. In figure 6, there are shown two curves, A and B, which illustrate the arc drop of two 12-anode rectifiers. Curve A applies to a rectifier of larger tank diameter than that to which curve B refers.

In connection with other electrical machines, usually an increase in size or capacity means an increase in efficiency, and it was therefore the desire of rectifier engineers for some time to obtain the same results with rectifiers. We therefore find that during the last few years when industry called for larger and larger rectifier units, rectifier tanks were used in multiple on common rectifier transformers, and that several large rectifier plants were installed with two, four, or even six tanks on one rectifier transformer. However, it was found that even this arrangement of sectionalizing rectifier units did not give the desired results in so far as arc drop or efficiency is concerned. The gain in efficiency did not justify the increase in number of auxiliary devices such as evacuating equipment, excitation and ignition devices, etc., which are necessary with the sectionalized rectifier.

Single-Anode-Tank Mercury-Arc Rectifier

INTERMITTENT IGNITION-EXCITATION

Recently an attempt was made to effect a low arc drop by sectionalizing the rectifier unit into as many tanks as anodes; in other words, each anode having its own individual tank. This design received a great deal of encouragement due to the introduction of a means for intermittent ignition which permitted the starting of the arc at any time during the positive half of each cycle. There are several ways to accomplish this, namely, by immersing the ignition anode (or ignitor as it is sometimes called) directly into the cathode mercury, or by using an insulated electrode (starting band) which may be either next to the cathode mercury or immersed in it but insulated from it. The first electrode arrangement permits initiating a cathode spot by discharging a relatively high current through the electrode and the latter accomplishes the same end by using a high-potential discharge. In one case an electrothermic-dynamic action produces the cathode spot; in the second case, it is a purely electrostatic phenomenon. With these devices it is possible to ignite each tank at the time the anode of that tank becomes more positive in voltage than the anode of any other tank comprising that particular rectifier unit. It was hoped that the use of such a method of ignition would reduce greatly the sensitivity to backfires in that no cathode spot, and therefore little or no ionization, would exist during the time the anode is at a negative potential.

This was accomplished by establishing a cathode spot anew during each cycle by means of current discharges which, however, have to take place over a very short time interval in order to keep losses at a minimum. In figure 2 is illustrated the means necessary for intermittent striking of the arc. Usually starting tubes T_1, T_2, T_3, etc. are used in order to effect the discharge at the proper time, and also concentrate the energy within a very small time interval so as to obtain a cathode spot with greatest intensity.

The sequence of operation may easily be seen in figure 2. As one of the main anodes A_1, A_2, A_3, in sequence, becomes more positive, the grid of one of the associated starting tubes T_1, T_2, T_3, etc. also becomes positive. When the potential on the anode of the starting tube reaches a predetermined value, current I_1, I_2, I_3 will flow to the respective ignition systems. This energy discharge causes an incandescent spot to be formed at the point where the ignition anode is immersed into the cathode mercury, causing electrons to be emitted from the latter. The main anode can then, if at the proper potential, carry current. As soon as the main anode begins to carry current the starting tube will extinguish, as the arc drop in the main arc is not sufficient to maintain a current through the starting tube. Hence the cathode spot initiated through the ignition anode discharge is maintained only as long as the main arc is firing and therefore has to be re-established every cycle.

Such a scheme has, however, shown several drawbacks, namely, the current necessary to establish a cathode spot of sufficient density is relatively large, and unless it is accomplished in a very brief interval, the losses become prohibitively large. If the cathode does not emit sufficient electrons, the cathode spot may not permit the main anodes to pick up current or then only after some delay in time. However, it is extremely important that all tanks pick up load at the correct instant during each cycle. Should any one tank fail to pick up load at the proper time, an unbalance in the transformer may take place which may cause high-frequency surges due to d-c saturation of the transformer core. Furthermore, if an anode does not fire at the proper instant, a very poor current distribution among the anodes may result, causing some of the tanks to carry undue overloads during this time interval. Another disturbance due to such a failure may consist of the generation of abnormal harmonics or excessive wave-shape distortion, see figure 3. During no-load and full-load periods, A and B, respectively, the anodes are firing in their normal sequence while during period C one anode failed to fire, resulting in a considerable dip in voltage.

Besides this, the successful operation of the ignition anode depends upon its im-

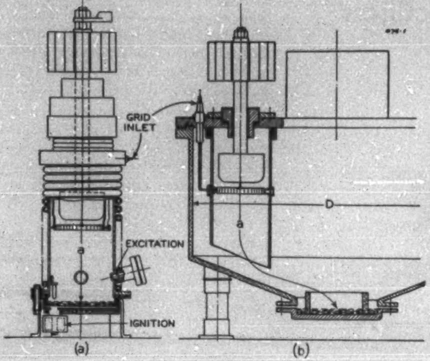

Figure 1. Cross section of a 600-volt Excitron and a conventional-type rectifier, illustrating anode, grid, and cathode assembly

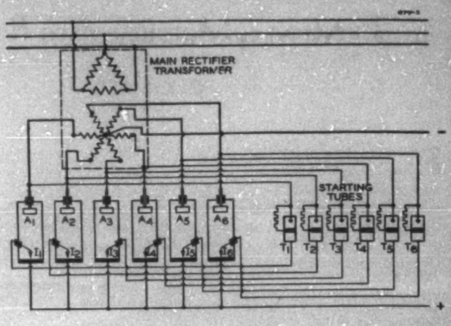

Figure 2. Typical ignitron-rectifier connection diagram showing six single-anode tanks

mersion into the cathode mercury of a very accurately maintained distance so that the heat density is localized in the immediate vicinity of the ignitor. Otherwise, the emission of electrons may not be sufficient for the main anodes to carry current or pick up at the proper instant. Therefore, the mercury level of the cathode in such single-anode rectifiers must be carefully maintained and should not be subjected to violent changes or vibrations which may disturb the depth to which the ignition anode should be immersed in the mercury. It may, therefore, be very difficult to use such a device on ships or locomotives where vibrations or fluctuations may affect the surface of the cathode mercury.

Continuous Ignition-Excitation

The main advantage usually referred to in connection with the intermittent-ignition rectifier is believed to be due to the fact that during the time the anode carries no current, and is subjected to a negative potential, there is no ionization in the tank. Several investigators have even thought this feature would make possible a rectifier design which would be practically backfire-proof, and would still permit locating the anode directly above the cathode, in this way reducing the arc length and, in turn, the arc drop. This deduction was probably based on the assumption that in the conventional multiple-anode rectifier a cathode spot and an arc are maintained during the time some of the anodes are at a negative potential. This arc and cathode spot cause ionization of the mercury vapor in the space under the anodes, which may become negative in potential; this ionization would then be responsible for increasing the backfire sensitivity. Extensive investigations on rectifiers operating on the test floor and also under actual load conditions have, however, indicated that such is not the case. It was found that the backfires in a conventional multiple-anode rectifier occur not only shortly after the anode has been carrying current and has been subjected to the maximum ionization, but also—much later in time. This and other considerations substantiated by extensive tests encouraged the Allis-Chalmers Manufacturing Company to build a six-anode rectifier, consisting of six single tanks using an ignition-excitation system for the main arc with a continuous cathode spot. In other words each tank will have some additional ionization besides the residue during the negative voltage period as a small current is maintained by an auxiliary anode. This type of rectifier has been called the Excitron rectifier.

Construction of the "Excitron" Rectifier

The construction of the anode and grid assembly is very similar to a commercial multiple-anode rectifier, as shown in figure 1. The grids are insulated from anode and tank and can be energized through a bushing, inserted near the anode. It was found advisable to insulate the cathode from the tank and to provide means for easy removability of this plate. The detachable anode plate can be eliminated, as the assembly of anode and grid can be done through the cathode opening.

The grids and shields are so designed and located that they provide adequate deionization and baffling. The ignition and excitation anodes are arranged and shielded in such a way so that little ionization is added to the residuum holding over during the negative-voltage period. It can therefore be seen that the design of the ignition and excitation system had to be based on somewhat different considerations than for the multianode rectifier. It would require a lengthy discussion to establish the theoretical basis for proving why a lower arc drop can be obtained in such a design than in a multianode tank, giving due considerations to the tendency of the rectifier to backfire. The arc drop can be made less in spite of the presence of grids and shields, at the same time the tendency to backfire would not be increased in spite of the direct exposure of the anodes to the cathode spot, and the splashing of mercury droplets from the cathode surface; this will be the subject of a separate future paper.

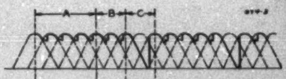

Figure 3. Direct-voltage wave shape with normal firing, with delayed firing, and if one anode fails to fire

The tanks are evacuated with a standard evacuating equipment consisting of a mercury-vapor and rotary oil pump, as shown in figure 4. The 6-tank set shown in this figure is rated 2,000 amperes at 600 volts, and if the number of tanks is doubled, a rating of 4,000 amperes and

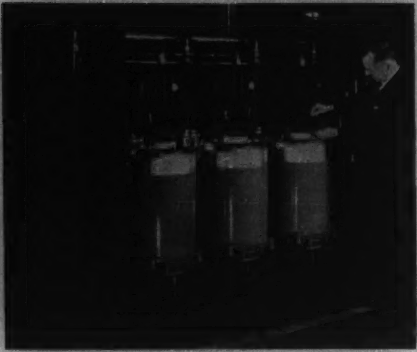

Figure 4. A 600-volt Excitron with control cabinet, evacuating and vacuum-measuring equipment

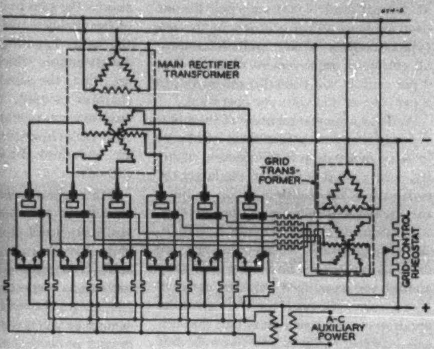

Figure 5. Typical Excitron rectifier connection diagram showing six single-anode tanks

600 volts would be obtained, which rating would correspond to a 12-anode multiple tank rectifier. Due to the fact that this rectifier has a very small thermal capacity because its weight per kilowatt is far less than that of a multiple-anode rectifier of the same rating, a special cooling system was developed which enabled this rectifier to be subjected to very heavy overloads and still maintain a safe operating temperature. The rectifier tanks are equipped with copper cooling coils which are connected to a mixing tank using a water-circulating pump.

Starting of the "Excitron" Mercury-Arc Rectifier

After extensive tests, it was found that a very small current can maintain a cathode spot of sufficient density and start the main arc firing exactly at the right instant of the cycle, even at very low temperatures of the tank. This was accomplished by a suitable selection for the location of the starting anodes. In order to make such a rectifier available for operation, an auxiliary arc is established only once by means of an auxiliary anode or anodes, controlled by automatic equipment. This auxiliary arc can be established with a smaller mercury-jet ignition consisting of a solenoid-operated plunger fitted over a tube and extending down from the cathode. If the coil is energized, a mercury jet is thrown up against an extension from the tank. As the jet collapses, an arc is established starting the auxiliary excitation arc. This arc will then maintain a cathode spot on the mercury and as soon as the main anode becomes energized, the power arc can flow to the individual anode. The establishing of the main arc will not depend on any delicate timing or tube equipment, but is accomplished by a most reliable device—namely, a transformer.

Figure 5 shows the diagram of connections of the auxiliary circuit. It can be seen that any kind of operating condition can be obtained by a proper interlocking of the ignition-excitation. The automatic control can be equipped with the necessary relays and time-delay devices in order to provide proper protection, restarting, and stopping of the cathode spot.

The control of the rectifier voltage can be effected by combining a variable d-c bias, supplied by a battery or obtained by a rheostat in a potentiometer connection from the rectifier bus and with an auxiliary source of alternating current for the grids, see figure 5. This imposes a d-c bias between the rectifier cathode and the neutral point of the grid-transformer secondary, so that the neutral point is at an adjustable d-c potential with respect to the rectifier cathode.

The operating voltage of the rectifier may be set at any desired value, so as to give the rectifier any suitable operating characteristic—drooping, flat-compounded, or overcompounded. This type of grid control was repeatedly described in connection with multiple-anode rectifiers and need therefore be referred to here only briefly.

The ability of a grid to prevent the flow of current from an anode during arbitrary time intervals makes it possible to use grids for completely interrupting the flow of current through the rectifier. When the grids of a rectifier are energized at a suitable negative potential, with respect to the cathode, the anode then carrying current continues to do so until its voltage becomes negative, when it will stop firing as a result of its valve action. The negative potential on the grids of the other anodes then prevents them from picking up the arc, and since the anode first considered will likewise be unable to again pick up the arc, the rectifier becomes blocked in a fraction of a cycle of the alternating voltage. The grids in the Excitron rectifier can therefore also be used for interrupting the current flow during abnormal operation, such as a short circuit, or backfire; for instance, applying a negative potential to the grid by using a relay which may be actuated from the primary or secondary circuit. It was found that the action of the grids is just as reliable in such a rectifier as it is in conventional multiple-anode units.

Further protective features are obtained by interconnecting the excitation circuit with the grid control circuit in such a way that the grids block the anodes from carrying current, and the cathode spot becomes extinguished by other means at the same time, so that the whole tank is made inoperative in the most reliable way, since there will be no ionization next to the anode and cathode.

Comparison of Arc Drop and Efficiency

In figure 6 are indicated the arc drops of two multiple-anode-type rectifiers, in curves *A* and *B*, each having 12 anodes, but having different diameters *D* (see figure 1*b*), and of a 12-tank single-anode rectifier, in curve *C*. It can be seen that at normal load, 4,000 amperes, the arc drop is about 40 per cent less in the new type of rectifier, which results in an overall efficiency improvement of about 3 to 4 per cent at 250 volts d-c and of $1^{1}/_{2}$ to 2 per cent at 600 volts d-c operation.

Another important feature of these new types of rectifiers is that there will be no increase in arc drop with increased capacity. As pointed out above, the larger the capacity of the multiple-anode rectifier, the greater the increase of the arc drop with capacity; see curves *A* and *B*. With single-anode tank units the arc drop stays the same no matter how many anodes are combined on one common transformer. Curve *C* therefore gives the arc drop of a 6-anode unit of half the indicated current rating or of a 24-anode unit of twice the indicated current rating.

Large multiple-anode-type rectifiers are at present being developed which have ring cathodes in order to avoid the above drawback, compare also figure 1, parts *a* and *b*. It will be interesting to see how the arc drop of single-anode tanks of different diameters will compare with each other and whether it will be possible to obtain a design having nearly the theoretical minimum arc drop without unduly increasing the tendency to backfires.

The efficiencies for the conventional and the Excitron type rectifiers at 600 volts are indicated in figure 6, curves *A′*, *B′*, and *C′*, respectively. It can be seen that at such a relatively high voltage the single-anode rectifier does not seem to present any considerable advantage.

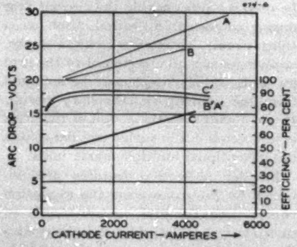

Figure 6. Comparative arc drop and efficiency curves of a double six-tank Excitron rectifier and of a conventional rectifier

Discussion of Relative Advantages and Disadvantages

Some of the advantages of these single-anode tank rectifiers over the conventional type are quite obvious as, for instance, the gain in efficiency and decrease of headroom required, and, furthermore, the easier handling of such units The disadvantages which may be mentioned are, first, the small volume of the arc chamber, second, the large amount of auxiliary equipment due to the fact that each tank requires means for igniting the arc, and, third, the necessity of a multiple cathode.

Other advantages as well as the disadvantages can, however, not be stated positively until a sufficient number of units have been operating on different kinds of loads, and for different types of services for some time. Some of the disadvantages, however, may be overcome or may be taken care of by the use of improved protective equipment. We have here in mind the small volumetric capacity of the individual tanks which may be a tremendous drawback in case a large reverse current has to be carried by the backfiring unit, causing in turn a very high vapor pressure. In such a case the possibility exists of reignition, especially in case of a very highly inductive circuit which may supply enough energy to cause an anode to fire over several cycles. Arrangements could be made, however, to feed this energy back into the a-c system, but it would usually necessitate a very complicated control system.

We would like to stress the fact in this connection that the above reasoning convinced us that it would be advisable to have an insulated cathode. The assumption, therefore, that an intermittent ignition permits the use of a noninsulated cathode (due to the arc being started at the point of the ignition anode and, therefore, unable to travel to the tank walls) may not be as correct as preliminary study may have indicated. However, only time will tell if it is advisable, even when using an intermittent ignition to connect the cathode directly with the tank, or if it would not be of advantage to use an insulated cathode, considering the above observation, during abnormal operation of rectifier plants.

Careful investigations have shown that a small excitation arc, properly arranged, etc., gives the same operating condition, as far as frequency of backfires is concerned, as with an intermittent ignition rectifier, and that, therefore, this rectifier may show in time several advantages over this ignitor rectifier. This type may especially prove to be less sensitive to the condition of the cathode, as, for instance, depth of mercury, disturbance due to vibration of the mercury surface, deposit of impurities on the surface, etc. Furthermore, there is no danger of disturbing the means of carrying the excitation arc and producing the cathode spot as there is when using the intermittent ignition. In the latter case, the ignition anode is continually exposed to the cathode spot produced by the main arc and will, therefore, be subjected to extremely high thermal stresses, especially during abnormal load conditions such as short-circuits, backfires, etc. The replacement of such an ignition anode may require only a short outage time, but it has to be kept in mind that there will be at least 12 such anodes in a unit of large capacity and a replacement, no matter how quickly accomplished, requires some re-forming.

Service Records

The unit as shown in figure 4, and other single-anode rectifiers of different diameters were in operation for several hundred hours at typical full-load and overload conditions similar to those encountered in electrolytic and railway service. The load was absorbed by a 600-volt 12,000-ampere motor generator set, and in case of a backfire, this set furnished reverse currents up to 40,000 amperes. The tests under such conditions can be considered as very severe and it was found that the unit met all requirements which were striven for when designing this rectifier.

During the last few months the unit has given very satisfactory service on a 625-volt railway system, where it is subjected to regular base load and overloads, but always carrying a good base load. In order to accomplish proper parallel operation the unit is practically continuously working with delayed firing, which means severe service for the anodes during the rectification cycle, as the commutating voltage with delayed firing is higher in value than when the anodes are left to fire in a natural way.

Conclusion

Shop and field tests show that a single-anode mercury-arc rectifier having continuous excitation can be just as reliable and free from backfires as a rectifier with intermittent ignition. Furthermore, it can be concluded that with this type of excitation the arc drop is as low as practically obtainable, being nearly equal to the cathode drop alone at light load (although the anode is located somewhat farther from the cathode) and is much lower than in a multiple-anode rectifier. Present experience with both types of single-anode rectifiers has definitely established the fact that reliable service

A New Electronic Multiplier for Power Frequencies

W. P. OVERBECK
ASSOCIATE AIEE

THERE are many electrical applications which require alternating current at higher frequencies than those normally obtained from the power lines. These applications include: induction heating, the operation of high-speed motors, and the operation of fog horns and underwater signaling devices. Although motor generators are satisfactory for most of this work, their inherent upper frequency limitations and need for mechanical maintenance have led to the development of several alternative methods of obtaining higher frequencies.

The inverter,[1] using mercury-vapor tubes, has the advantage of high efficiency but has an upper frequency limit in the neighborhood of 1,000 cycles, due to deionization time of the tubes. Even at lower frequencies, occasional failures occur.

The vacuum-tube oscillator[2] is more reliable than the inverter but must operate at very high voltages in order to obtain good efficiency. The inverter and vacuum-tube oscillator both have the additional disadvantage of requiring large energy-storage elements in the output circuit due to the fact that direct power transfer from input to output occupies only a small portion of the output frequency cycle.

Saturable-reactor frequency changers[3] have been built to operate at very good efficiency. The most efficient forms are used to triple the input frequency. Their principal disadvantages are: poor voltage regulation at the output, poor input power factor, and heat dissipation problems brought about by the requirement of high flux densities.

This paper describes a new electronic frequency multiplier which also has a few disadvantages but, at the same time presents certain advantages which the above devices do not have. These are:

1. Although it employs gas-filled tubes, its upper frequency limit and reliability are not influenced by deionization effects.
2. It does not require large energy-storage elements at the output because power is transferred directly from input to output during half of each output cycle.
3. It provides very good regulation of output voltage.
4. It is stable under all conditions, including transient overloads or input voltage variations.

An incidental feature of the circuit is that it may be used to convert multiphase power to single-phase power with balanced loading of the multiphase lines.

Fundamental Circuit

Figure 1 shows the circuit of the simplest form of the new electronic frequency multiplier, a circuit which will convert single-phase power to single-phase power at double frequency. It is similar to a single-phase full-wave rectifier except that the terminals which would normally be the d-c output terminals are connected to the primary of an output transformer. The tubes are of a controllable type such as the Permatron, thyratron, or ignitron. The tubes which are illustrated are permatrons, which appear to be more readily adaptable to the circuit. These tubes have been described in detail elsewhere[4] and all that need be said here is that their behavior is similar to that of thyratrons except that the instant at which they start conducting is controlled by an externally applied magnetic field rather than by potential applied to an internal grid. Magnetic control is indicated in the diagram by the coil adjacent to each tube. Conduction through the Permatron starts at the instant that the magnetic field, produced by this coil, becomes smaller than a certain critical value which depends on the voltage between anode and cathode. A greater field strength, regardless of its polarity, will prevent the starting of conduction.

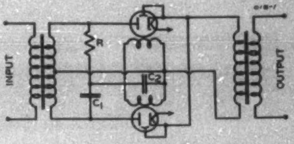

Figure 1. Fundamental circuit-electronic frequency doubler

R and C_1—Phase-shift control circuit
C_2—In resonance with control coils

A mathematical theory of the operation of the electronic frequency multiplier has been developed. This analysis takes into account the voltage drop through the tubes and the losses caused by circulation of direct current through the tubes and output transformer primary. The fundamental idea, however, is best explained by temporarily neglecting these complicating factors.

If the tubes are adjusted to start conduction or "fire" at a delay of nearly 90

---

and some economy can be expected, especially at voltages below 600 volts, and in installations where, during a backfire, no, or only very little, backfeed current can enter the backfiring tank.

It was also definitely established that in spite of the small size of the tanks, which allow storing of only very little heat energy, considerable overloads can be carried if a sensitive high-speed cooling system is employed.

Furthermore, operation under fluctuating as well as continuous loads has shown that no concern need be felt that failures of excitation may cause undue overloading of the transformer secondary windings.

At present there seems to be a number of applications for which each type of rectifier—the multiple-anode and the single-anode—is best suited. Experience may, however, show in time that the single-anode rectifier may be suitable for applications where the conventional type at present seems to be more favorable. Although the conventional type may always have its place in the electric-power field, yet the development of the single-anode tank may open up new applications in the low-voltage and probably also in the very high-voltage field.

Discussion

For discussion, see page 1168.

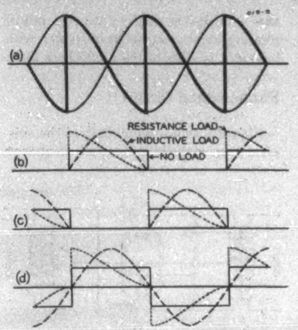

Figure 2. Voltage and current relations in the electronic frequency doubler

(*a*)—Formation of output voltage wave

(*b*) and (*c*)—Plate transformer secondary currents

(*d*)—Input currents

degrees, the voltages throughout the circuit are as shown on axis *a* of figure 2. The plate-transformer secondary voltages each side of center tap, are indicated by two sine waves 180 degrees out of phase. Each tube starts to conduct just before the peak of the positive half cycle of its associated secondary, and, due to the inductance of the output-transformer primary, continues to conduct until the other tube starts. Thus, the voltage across the primary of the output transformer is represented by the heavy line. This wave has a fundamental frequency which is double the line frequency and contains a small d-c component which is required to maintain the d-c flow through the output transformer primary. Each tube supplies alternate cycles of the output voltage.

With no load across the output, the current pulses through the tubes are approximately as shown by the solid waves on axes *b* and *c* of figure 2. These pulses are square topped if the inductance of the output transformer primary is large When a load is connected to the output, it reflects a current component into the primary of the output transformer which produces a resultant wave form as shown by the dotted line for a resistance load and by the dashed line for an inductive load. The maximum load is such that the peak amplitude of the reflected load current just balances the amplitude of the square-wave no-load current. An output load greater than this will cause each tube to stop before the next tube starts by forcing the current to zero. Axis *d* of figure 2 shows the current wave forms as reflected to the primary of the input transformer for no load and for full inductive and resistance load at the output.

Thus, the fundamental principle of operation is that energy is supplied to the load from the input power line during the positive half cycles of output voltage and that the energy in the negative half cycles is supplied from energy stored in the output transformer during the positive half cycles.

For higher-frequency output, similar circuits may be developed from multiphase rectifier systems as shown by figure 3, a circuit used for tripling the line frequency, and which, incidentally, gives a single-phase output with balanced loading of the three-phase line. More complex circuits are described below for obtaining multiphase output and higher frequency output. In general, the number of controllable discharge paths required is equal to the frequency multiplication factor times the number of output phases.

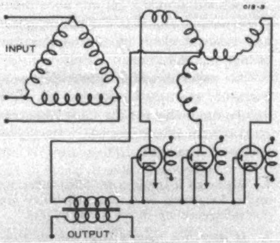

Figure 3. Fundamental circuit of frequency tripler

Output-Transformer Inductance

In a previous paper[3] the writer has described a method of computing the "critical" value of the input choke in a filter system for a rectifier using controllable gas-filled tubes. The critical value of inductance is that which is just sufficient to insure that each tube in the rectifier system will continue to conduct until the next tube starts. With an inductance of this value at the input to the filter, the current through each tube approaches zero at some instant during the period of conduction of each tube.

The output-transformer design in the frequency multiplier is a similar problem, since the primary inductance of this transformer has the same effect in controlling conduction through the tubes. However, under no-load conditions in the frequency multiplier it is required that in addition to remaining continuous, the current must remain practically constant, and never approach zero. Thus, the primary inductance of the output transformer must be much greater than the critical value.

The formula, derived for computing the critical value of inductance, was based on the assumption that the d-c output voltage of the rectifier was constant and free from ripple. In the frequency multiplier, the corresponding direct voltage is the voltage drop due to the d-c circulating current through the output transformer. Since it is required that this current be practically constant, being made up of a succession of square-topped waves from each tube, the d-c output voltage is also constant and the same assumptions as used for computing critical inductance are valid. The formula for critical inductance at large angles of firing delay is:

$$\omega L_c/R=(1+D/E_{dc})(1-\pi/n\ \cot\ \pi/n)\ \tan\ \theta$$

where:

$\omega=2\pi$ times the input line frequency
$L_c=$ value of critical inductance (henries)
$R=$ output load resistance (ohms)
$D=$ drop through tubes (volts)
$E_{dc}=$ d-c output (volts)
$\theta=$ firing delay angle (radians)
$n=$ number of tubes or rectifying phases

Further mathematical work, given in detail in the appendix, has shown that it is also possible to compute the value of inductance required to keep the current through the tubes from dropping below a given fraction, K, of the amplitude of the ideal square-topped wave. This value of inductance is given by the equation:

$$\omega L/R=(\omega L_c/R)/(1-K)$$

A more complicated relation is obtained for small angles of firing delay, but the above equations are of most interest in the frequency multiplier where the firing delay is always of the order of 90 degrees. The accuracy of the second equation becomes greatest as K approaches a value of one.

The impossibility of obtaining the type of operation described above with a firing delay of exactly 90 degrees is illustrated by the fact that this value of θ gives a value of infinity for the required inductance. In multiphase circuits where n is greater than two, the ideal firing delay angle is still 90 degrees. Firing delay in multiphase systems, however, is measured from the normal commutation point of the tubes rather than from the time of zero voltage across the associated secondary of the plate transformer.

Table I

Multiplying Factor	Output Frequency (From 60 Cycles)	Approximate Efficiency (Per Cent) K = 0.9 ωL/R = 100	Output Voltage Analysis $\left(\frac{\text{RMS Values}}{E_{\max}}\right)$			
			Total	Fundamental	Second Harmonic	Third Harmonic
2	120	90.5	0.707	0.600	0.290	0.154
3	180	94.0	0.542	0.439	0.200	0.131
4	240	95.6	0.427	0.342	0.162	0.107
6	360	97.2	0.294	0.232	0.113	0.075
10	600	98.2	0.179	0.141	0.070	0.046
20	1,200	99.3	0.095	0.071	0.035	0.024

In all cases, when each tube continues conduction until the next tube starts, the d-c output voltage is given by the equation:

$$E_{dc}=\frac{nE_{\max}}{\pi(1+D/E_{dc})}\sin\pi/n\cos\theta$$

Thus, a firing delay approximating 90 degrees is ideal in the frequency multiplier because it results in a small d-c component of voltage across the output-transformer primary. The principal design problem is to determine the closest approximation to a 90-degree delay which may be obtained with finite values of inductance of the output transformer.

Since the load resistance, R, is the d-c resistance of the output transformer primary, it is possible to determine immediately the maximum firing delay which may be obtained because the value of $\omega L/R$ is fixed by the wire size and core dimensions of the output transformer. In practice, $\omega L/R$ may be as high as 200. Note that it is the d-c resistance rather than the a-c resistance which affects the present analysis. The added resistance due to core losses has its effect mainly in reducing the available power output. To obtain maximum values of inductance with the least amount of material, the transformer design must follow the same principles as used in designing rectifier filter chokes. The presence of d-c magnetizing current necessitates an air gap in the core. General principles of this type of design have been given by C. R. Hanna and R. F. Edgar.[6,7]

Efficiency

The limitation of $\omega L/R$ of the output transformer defines the maximum firing delay and thus determines the direct-voltage component across the primary winding. The d-c circulating current is determined directly from the output current, and the voltage ratio of the output transformer, since it must balance the reflected peak amplitude of output current. The losses due to this circulating current are equal to its product with the direct-voltage component across the output-transformer primary, plus the voltage drop through the tubes. These losses are the only ones which are essentially due to the method of frequency conversion. Copper losses and core losses in the two transformers are of the same order of magnitude as is encountered in all transformers, and have not been taken into account in computing theoretical efficiency.

On this basis, the equation obtained for efficiency is:

$$\text{Per cent efficiency}=100/(1+N)$$

where N is given by the equation:

$$N=3n/2\pi\div\sqrt{1+\left(\frac{(1-K)\omega L/R}{(1+D/E_{dc})(1-\pi/n\cot\pi/n}\right)^2}$$

A detailed derivation of this equation is also given in the appendix.

Estimated values of efficiency, obtained from these equations, are given in table I for various values of n and for $\omega L/R=100$. For convenience, the resulting values of output frequency for the different values of n are given for a 60-cycle line frequency. The table indicates extremely high efficiency at the higher output frequencies. This should not, however, be misunderstood. It is doubtful that such high values would be possible in practice because, as shown later, the input power factor becomes so poor at the higher output frequencies that losses due to circulatory currents would, in an economical design, reduce efficiency to a very large extent.

Output Characteristics

One of the most favorable qualities of the electronic frequency multiplier is its regulation to load. As long as continuous conduction is maintained through the tubes, the output voltage wave must follow the wave form of the plate-transformer secondaries. Any drop in output voltage from no load to full load is entirely due to resistance and leakage inductance of the transformers. The voltage drop through the tubes remains practically constant at all loads.

The output wave form remains constant from zero to full output load and its characteristics may be easily determined. Table I includes values of rms alternating voltage across the output transformer primary, rms values of the fundamental component, and rms values of harmonic components, all as a function of the frequency-multiplying factor. The presence of harmonics may require filtering of the output for some applications, but in others it is not detrimental. For example, in driving induction motors the presence of third harmonics in the applied voltage up to 30 per cent of the fundamental increases the losses by only 2 per cent of the motor input.[8]

Input Characteristics

One point which is often overlooked in applications of gas-filled control tubes is the fact that delayed firing produces a low input power factor and distortion of the current wave form makes it difficult to correct for bad power factor. In the electronic frequency multiplier, this situation is partially overcome by the fact that conduction is maintained through each tube for as long a period as possible. However, due to the abnormal firing delay, poor input power factor is one of the principal drawbacks of the circuit. At low output frequencies, the input power factor, uncorrected, is better than at high output frequencies. On the other hand, the input-current wave form is better at the higher output frequencies. These two factors, working in opposite directions, result in the fact that, at all output frequencies, it is possible to correct power factor to better than 80 per cent. The higher output frequencies, however, require more correction. For example, at 960 cycles output, power factor correction requires seven kva per kilowatt output.

Experimental Results

The fundamental idea and theoretical performance of the electronic frequency multiplier were obtained entirely through mathematical work, previous to any experimental work. Thus the initial tests were made principally to establish finer points in the design and to determine the behavior of the circuit under unusual conditions such as transient variations in input voltage and load.

The tests were made on the single-phase frequency-doubling circuit of figure 1. Adjustment of the circuit was accomplished by setting the firing delay of the tubes at an angle less than 90 degrees and with a variable resistor in series with the output transformer primary. The firing delay was increased by steps while the variable resistor was reduced sufficiently to keep the direct current up. Eventually, the variable resistor was reduced to zero and taken out of the circuit. A small final adjustment of firing delay was made in order to set the direct current at the required value. The adjustment process was found to be simple if the direct current is kept under observation and if an oscilloscope is connected across the primary of the output transformer. The voltage wave form across this transformer is as indicated in figure 2 except when either tube fails to continue conduction until the other starts. In that case, the wave takes a short cut across the lower corner as shown in figure 4. Having reached the final adjustment at no load, an output load was applied in steps to obtain data on regulation and efficiency.

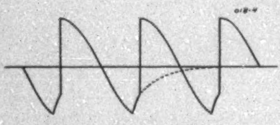

Figure 4. Effect of overload on output waveform of frequency doubler

During the course of the tests, it was found that the direct current showed a tendency to drift. This is due to the fact that an extremely small shift in firing angle, such as might be caused by shifting of tube characteristics or control-magnet characteristics by temperature changes, will cause a relatively large shift in direct current. This tendency was corrected by adding an auxiliary winding to each control magnet and allowing the direct current to flow through these coils in such a direction as to cause a shift in firing delay to counteract any shift in current. The two auxiliary windings were connected in opposition so that the alternating voltages induced by the a-c control flux were balanced out. This automatic correction is very effective regardless of load conditions and is the principal reason why the use of Permatrons is preferred. If thyratrons are used, a similar action may be obtained by adding a resistor in series with the common cathode connection and returning all the grid circuits to the end of the resistor which is connected to the output-transformer primary. This method adds appreciably to the losses. Theoretically, the regulation obtained by such circuits is best when the feedback of d-c control is greatest. However, due to the time constant of the circuit elements, instability results unless the a-c control predominates.

Previous to the test, the value of $\omega L/R$ of the output transformer was estimated as 183 from its inductance at 60 cycles and its d-c resistance. Computing backward from the results obtained, it was found that its effective value was 232. The discrepancy is due to the fact that its operating conditions with a large d-c magnetizing component and a 120-cycle voltage of unusual wave form are difficult to reproduce.

Data obtained by varying the load from zero to full load are plotted in the curves of figure 5. Efficiency values are not as high as might be obtained because the tubes were operating at a low voltage level in comparison to their rating. This is illustrated in figure 5 by the large proportion of the total losses which are due to tube loss. These curves are not affected by the addition of the d-c regulating coils, because the direct current remains practically constant throughout the entire load range.

At overloads, the output voltage, due to the alteration of wave form, illustrated in figure 4, drops rapidly because the tubes fail to conduct for a full half cycle. The dotted line in figure 4 is placed there to indicate the fact that the "kink" in output voltage under overloads follows the natural decay curve of the output-transformer inductance and the load resistance. An extended regulation curve is shown in figure 6. This curve was made with the d-c regulating coils connected so that the drop in voltage is more rapid than it would be without them. In most cases, this is an advantage because it protects the circuit from damage due to momentary overloads. The direct current rises during overloads because failure of the tubes to conduct continuously produces an increase in the d-c component of voltage across the output-transformer primary.

Several transient effects were investigated. When the power is switched off and on at the input to the plate transformer, the output voltage responds rapidly. When the switch is first closed, the output voltage rises to practically full value in less than one cycle. The first four cycles of output voltage indicate that conduction through the tubes is not quite continuous. By the fifth cycle, operation is substantially at steady-state conditions. Switching the load on and off at the output has no apparent effect if the load is at full value or less. Overloads up to a short circuit produce a transient drop in output voltage which recovers almost immediately when the overload is removed. If one tube fails to conduct, the output voltage drops to half its normal value but recovers as soon as conduction is resumed.

The final conclusion reached from ob-

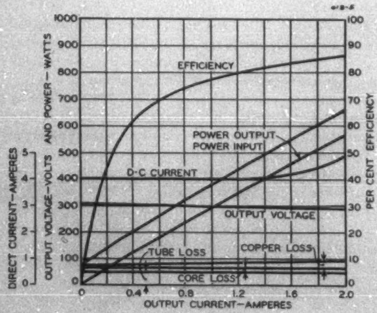

Figure 5 (left). Performance of experimental frequency doubler

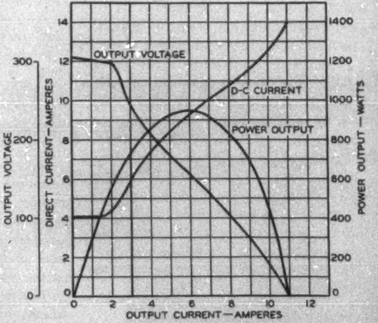

Figure 6 (right). Overload performance of experimental frequency doubler

servations of such unusual conditions was that the circuit is thoroughly stable and has none of the characteristics observed in vacuum-tube oscillators or gas-tube inverters where it is possible to destroy oscillations under transient conditions and which must always be placed in operation according to a fixed schedule. Its general behavior is as good as that of any rectifier system. Transient regulation to load is far better than may be obtained with either motor generators or filtered rectifiers because, under normal load conditions, the output is electrically connected to the input at every instant.

During the tests, it was also realized that the high efficiency at full load may be extended to lighter loads by making a slight adjustment in firing angle so that, when the load is reduced, the direct current is reduced simultaneously. In a large unit, it would be feasible to make this adjustment automatic through a regulator system actuated by the output current. The simplest method is to rectify the voltage from the secondary of a current transformer in series with the output and to apply the resulting direct current to a third winding on each control magnet. The output of this auxiliary rectifier should be shunted by a large capacitor in order that the automatic regulation may depend on the peak value of output current rather than the average value. The current wave form varies with the type of load while the maximum output of the frequency multiplier is dependent on peak output current.

Applications

The most immediate application for the frequency multiplier is for operation of high-speed motors. Practically all high-speed motors are of the three-phase induction type. Figure 7 shows a circuit which has been developed for producing a triple-frequency three-phase output. There are three groups of three tubes, each group being phased 40 degrees apart from the others in terms of the input frequency. At the output frequency, the voltages are 120 degrees apart. The plate transformer converts the three-phase input to nine phases and its secondary windings are distributed to give the optimum utilization of windings and to avoid d-c magnetization of the core.

One possible advantage of this combination of frequency multiplier and motor is in its application in industries where the product is made in a continuous strip such as is the case with rayon or paper. In both cases, the thread or paper passes through stages where its tensile strength is not fully developed and slight variations in speed may cause trouble. In operating such a factory, the use of a synchronous motor generator driving synchronous motors represents a two-stage problem in hunting, prevents the installation of separate units at different points, and often requires mechanical linkage between several machines. If electronic frequency multipliers are used, each remains in accurate synchronism with the power line. The hunting, represented by small shifts in firing delay of the tubes, is less than 0.1 degrees of the low-frequency cycle.

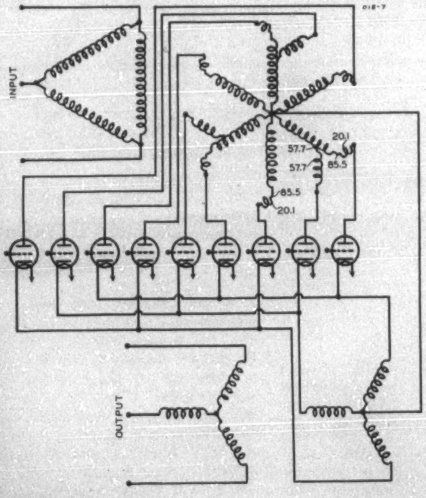

Figure 7. Electronic frequency tripler with three-phase output

One application to which the frequency multiplier appears to be especially adaptable is the operation of equipment using motors designed for 50–60 cycle operation in 25-cycle districts. There are several such cases in which it has been found better to add an auxiliary frequency converter than to redesign the equipment to accommodate an occasional 25-cycle motor installation.

A second field of application is that of induction heating. Preliminary cost estimates indicate that, at frequencies in the region of 1,000 to 2,000 cycles, it is doubtful that the electronic frequency multiplier would cost less than a motor generator, especially when the cost of power-factor correction is included. An experimental setup of 16 small tubes indicated, however, that reliable operation may be readily obtained at an output frequency of 960 cycles. At lower frequencies, an advantage in cost may be shown. Applications for low-frequency induction heating include those such as the baking of enamel on steel automobile parts.[9]

Conclusions

The experimental work, at its present stage, is sufficient to show the validity of the mathematical analysis represented by the first few sections of this paper. In adapting the circuit to applications, such as those mentioned above, some simplification should be possible. For example, the windings of a high-speed motor could be so designed and connected as to avoid the need of the output transformer of the frequency multiplier.

Appendix

Inductance Formulas

The formula for critical inductance is derived from an expression for the current in each tube of an n-phase rectifier. During the period of conduction, this current is given by:

$$i = E_{\max}/\omega L\left[\sin(\omega t - \pi/n) - \frac{n\omega t}{\pi}\cos\theta\sin\pi/n + C\right] \quad (1)$$

where:

$E_{\max}$ = peak secondary phase voltage (volts)
$\omega = 2\pi$ times the line frequency (cycles per second)
n = number of anodes or rectifying phases
t = time (seconds) and is equal to zero at the normal time of firing without delaying control
θ = firing delay angle (radians)
C = a constant of integration

In evaluating the critical inductance, the constants, C, is determined by setting i equal to zero at the instant at which the voltage across the choke passes through zero. When the inductance is greater than the critical value, this instant no longer corresponds to zero current but to minimum current. If the minimum current is assumed to be a certain fraction, K, of the average direct current, and A is the value of ωt at which the choke voltage passes through zero, then:

$$KI_{dc}=E_{\max}/\omega L\left[\sin(A-\pi/n)-\frac{nA}{\pi}\cos\theta\sin\pi/n+C\right]$$

and

$$C=\frac{nA}{\pi}\cos\theta\sin\pi/n-\sin(A-\pi/n)+\omega LKI_{dc}/E_{\max} \qquad (2)$$

L is now, by definition, limited to the value which produces a minimum current equal to KI_{dc} and is determined by integrating equation 1 over the period of conduction and setting its average value equal to the direct current. This process leads to the equation:

$$\omega L/R=\frac{(1+D/E_{dc})}{(1-K)}\times\left[\tan\theta-\theta-\pi/n+A-\frac{\pi\sin(A-\pi/n)}{n\cos\theta\sin\pi/n}\right] \qquad (3)$$

where:

D = drop through tubes (volts)
E_{dc} = d-c output voltage

This form of the equation requires the substitutions:

$$E_{dc}+D=\frac{nE_{\max}}{\pi}\cos\theta\sin\pi/n \qquad (4)$$

and

$$R=E_{dc}/I_{dc}$$

For large firing delay angles, such as required in the frequency multiplier, A equals θ so that:

$$\omega L/R=\frac{(1+D/E_{dc})}{(1-K)}\tan\theta(1-\pi/n\cot\pi/n) \qquad (5)$$

Efficiency Formulas

Since the limiting factor in equation 5 above is the value of $\omega L/R$, the firing angle is given by:

$$\tan\theta=\frac{(1-K)\omega L/R}{(1+D/E_{dc})(1-\pi/n\cot\pi/n)} \qquad (6)$$

At this firing angle, we have, from equation 4:

$$E_{\max}=\frac{\pi E_{dc}(1+D/E_{dc})}{n\cos\theta\sin\pi/n} \qquad (7)$$

The peak output voltage of the frequency changer, referred to the primary winding, is $E_{\max}\sin\pi/n$. Assuming the output voltage to be a saw-tooth wave, the power output into a pure resistance load is:

$$\left.\begin{aligned}&W_o=\frac{2}{3}E_{\max}I_{dc}\sin\pi/n\\&\text{or}\\&\frac{2\pi E_{dc}I_{dc}(1+D/E_{dc})}{3n\cos\theta}\end{aligned}\right\} \qquad (8)$$

The saw-tooth-wave assumption is favorable to a frequency doubler but becomes increasingly accurate as the output frequency increases. Substituting from equation 6 for $\cos\theta$:

$$W_o=\frac{2\pi E_{dc}I_{dc}}{3n}\times\sqrt{(1+D/E_{dc})^2+\left[\frac{(1-K)\omega L/R}{1-\pi/n\cot\pi/n}\right]^2} \qquad (9)$$

The d-c losses are given by:

$$\left.\begin{aligned}&W_1=(E_{dc}+D)I_{dc}\\&\text{or}\\&E_{dc}I_{dc}(1+D/E_{dc})\end{aligned}\right\} \qquad (10)$$

Thus, the fractional losses in terms of power output are given by:

$$N=\frac{W_1}{W_o}=\frac{3n}{2\pi}\div\sqrt{1+\left[\frac{(1-K)\omega L/R}{(1+D/E_{dc})(1-\pi/n\cot\pi/n)}\right]^2} \qquad (11)$$

And the efficiency is given by:

$$\text{Per cent efficiency}=1/(1+N) \qquad (12)$$

Dynamoelectric Amplifier for Power Control

E. F. W. ALEXANDERSON
FELLOW AIEE

M. A. EDWARDS
NONMEMBER AIEE

K. K. BOWMAN
NONMEMBER AIEE

THE USE of amplifiers has become common knowledge in radio, but on the other hand, the term amplification has seldom been applied to processes in power engineering. Strictly speaking, we may say that a radio amplifier is only a form of control because we always tap a new source of power and the function of the amplifier is to control this power so as to reproduce the changes of energy flow at a higher power level. On this ground we might say that an ordinary d-c generator is an amplifier because we control the power output by the current in the field winding. Such a terminology would, however, be rather misleading because when we say amplification, we imply something more specific than when we say control. An amplifier should give accurate reproduction both of intensity and time intervals, whereas, controlled power circuits used so far have not met these requirements. In the radio-frequency amplifier we are dealing with a time element of less than a millionth of a second. In an audio amplifier the time element is about $^1/_{1,000}$ of a second. The only device we know of that will respond in such a short time is the high-vacuum electron tube. In power circuits, on the other hand, the time element is seldom less than one-tenth of a second.

When it became apparent that amplifiers were needed in power engineering we naturally turned to the vacuum tube. It was found, however, that the high-vacuum tube used in radio did not lend itself so well to high power circuits as the mercury-vapor and gas-filled tube with grid control known as the thyratron. The thyratron amplifier has found many successful uses in power applications and it was in fact this demand that led us to consider what other means may be available to solve similar problems. In the thyratron amplifier we have a device with an extremely high ratio of amplification so that for most practical purposes only a single stage is needed.

A thyratron amplifier may be controlled from a small regulator and may be used to furnish excitation of large synchronous machines. Installations of this type have proved very successful in service and are found superior to the conventional exciter plant in giving quick response to sudden changes of load. From an engineering standpoint, this type of installation is highly successful. Unfortunately, in the present stage of its development, the costs are such that it is not justified economically.

The type of dynamoelectric amplifier which will be described was developed to meet new control functions in industry where a high rate of amplification must be combined with a quick and accurate response. As an approach to this problem we were again guided by the history of radio amplification. It was found in the design of radio amplifiers that the ratio of amplification or the sensitivity can be increased within certain limits by sacrifice of the quickness of response. Thus an improvement of ten to one in sensitivity might be gained by permitting the process to take ten times as long. The same general principle applies to the dynamoelectric amplifier. In radio we have found, however, that by using amplification in several stages we can gain in sensitivity in geometric progression without sacrifice of speed of response. The dynamoelectric amplifier which for brevity has been called "amplidyne" generator, has been developed on this principle. It is a two-stage amplifier incorporated in one dynamoelectric machine. In its physical structure it resembles the Winter-Eichberg motor, the Rosenberg generator, and the Pestarini metadyne, characterized by a pair of short-circuited brushes at right angles to the power brushes. In its functions, it is quite different. The first stage of amplification is from the control field to the short-circuited brushes and the second stage from the short-circuited brushes to the power brushes.

Figure 1. Functional diagram of the dynamoelectric amplifier (amplidyne generator)

Figure 1 shows a functional diagram of the dynamoelectric amplifier (amplidyne generator). The principal elements are:

A control field

A short-circuit axis on the armature

An output circuit from the armature including a compensating winding

A high ratio of amplification of the order of 10,000 to 1 can be realized by this system. The over-all amplification is the product of an amplification of about 100 to 1 between the input winding and the short-circuit axis and another of 100 to 1 between the short-circuit axis and the output axis. The process of amplification in two stages can be further explained by assuming that the magnetic flux which generates the voltage in the short-circuit axis may be made only one-tenth as strong as flux in the power axis. Therefore the volt-amperes required to produce the control flux need be only $^1/_{100}$ as great as if the power field were excited directly from the control circuit. The control circuit may therefore contain enough resistance in proportion to its reactance to realize the desired short time constant.

The diagram also shows that the output circuit is on the same magnetic axis as the control circuit. There may be thus a direct magnetic back coupling from the output circuit to the control circuit with the tendency to regeneration and oscillations with which we are familiar in radio amplifiers. The object of the compensating winding is to neutralize this back coupling. That this is a rather delicate adjustment may be realized when it is remembered that the volt-amperes in the output circuit may be more than 10,000 times as great as the volt-amperes in the control circuit.

We also find that a compensation which is correct for direct current in the steady state may not be right for transients or alternating current. In the design of an amplifier system we must therefore take into account not only the characteristics of the machine itself but also the circuits

Paper 40-7, recommended by the AIEE committee on industrial power application, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 8, 1939; made available for preprinting November 29, 1939; released for final publication March 15, 1940.

B—Load volts
C—Load current

with which it is associated and we must analyze the performance of the system from the point of view of a-c and transient stability as well as d-c stability.

The reaction of the output circuit upon the input circuit with alternating current is under certain circumstances opposite to the reaction from direct current. This statement may seem surprising and need some further explanation. Let us assume that the machine is so designed that the back-coupling action for direct current is negative which produces stable operation for the steady state. Let us now assume that we use this same machine for amplification of alternating current and that we deliver the power to an inductive circuit like the field of a synchronous machine. Under those circumstances the back-coupling effect for alternating current may be positive, and cause regenerative oscillations at a critical frequency. The reason for this is that the alternating current in the output circuit is displaced more than 90 degrees from the current in the control circuit, thus reversing the back coupling from negative to positive. This positive reaction is regenerative and may result in continuous oscillations, as shown on oscillogram figure 4.

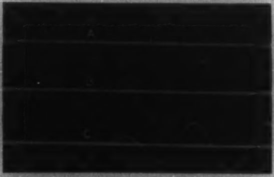

Figure 3. Effect of back coupling in undercompensated amplidyne generator when closing load circuit

A—Control-field volts, 60-cycle timing wave
B—Load volts
C—Load current

Figure 2 shows a correctly compensated machine feeding an inductive load. No back coupling between the load circuit and the control circuit is noticed when the load circuit is closed. The operation is perfectly stable and there is no tendency to oscillate.

In contrast to this, figure 3 shows the behavior of the same machine when undercompensated. The action of the load current upon the control flux is shown by a substantial increase of the output voltage due to regeneration. This is in contrast to a reduction in output voltage when a steady d-c load is applied. When the control field is open-circuited the machine passes from forced oscillations at four cycles per second to free oscillations at seven cycles, as shown in figure 4.

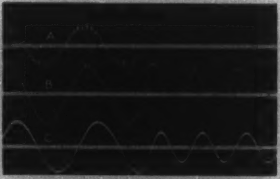

Figure 4. Free oscillations in undercompensated amplidyne generator when opening control circuit

A—Control field volts, 60-cycle timing wave
B—Load volts
C—Load current

Such tests with alternating current are convenient for analyzing and defining the amplifier characteristics. In most cases of practical application we are however dealing with rapid control transients in a generally unidirectional flow of current. Figure 5 shows an oscillogram taken of a typical machine. In this test the control field voltage was applied instantaneously. The field current did not build up instantaneously due to the inductance of the control field. However, the short-circuit-axis current and load voltage are nearly in phase with the field current. Hence, the time constant of the machine is only slightly larger than that of the control field and is not the numerical sum of the time constants of the control field, short-circuit axis, and load. This fact has been proved both experimentally and mathematically. The overall time constant of the amplifier shown on this record is $^1/_{30}$ of a second.

The tendency toward regenerative oscillations is present when the dynamoelectric amplifier feeds a highly inductive load such as the field winding of a large machine. If the desired combination of d-c stability and a-c stability has not been realized in the design of the machine it is possible to overcome the difficulty by adding an external back coupling which functions only at transient and alternating current. In most cases, however, this expedient is not needed. No case has however been found where it was not possible to adjust the system for stable operation in one way or another.

A theory of oscillations and the methods for avoiding them to be complete should take into account the effect of capacity as well as inductance in the output circuit. Electrostatic capacity in low-voltage circuits is so small that it may be neglected, but effects equivalent to capacity are apt to be present to an extent that becomes important in the functioning of the system. The mechanical inertia of a d-c armature reacts upon the circuit like an electrostatic capacity with the only difference that it is usually so much greater that it may be measured in farads instead of microfarads. Electrostatic capacity in conjunction with electromagnetic inductance produces tuning effects at a natural period in accordance with the well-known formula

$$\text{frequency} = \frac{1}{2\pi\sqrt{LC}}$$

When we use a dynamolectric amplifier to deliver power to a d-c motor we have a practical case of that sort. The inductance of the armature winding of the generator plus the inductance of the motor winding create a natural period of resonance in conjunction with the electromechanical capacity which is determined by the inertia attached to the motor shaft. In practical systems this natural period is of a magnitude of a few

The Design Characteristics of Amplidyne Generators

ALEC FISHER
ASSOCIATE AIEE

COMPANION papers present some of the inherent possibilities and the useful applications for dynamoelectric amplifiers.[1,2] They have also clearly pointed out that the inherent value of such an amplifier is determined by three characteristics: (1) ratio of response or sensitivity; (2) speed of response; and (3) stability.

This paper describes the essential design features of two-stage dynamoelectric amplifiers, known as "amplidyne" generators, which enable satisfactory values for these three characteristics to be obtained. Typical performance curves and oscillograms are shown, indicating the type of performance that has been found satisfactory in service.

Preliminary Analysis

The amplidyne generator is fundamentally an armature-excited machine, in that the armature is essentially the source of main excitation, and it is also the source of main power output. The first stage of amplification is from the control field to the short-circuit axis and the second stage from the short-circuit axis to the power-output axis. The total amplification is equal to the product of first and second stage amplification.

Figures 1*a* and 1*b* show a two-pole d-c armature with two pairs of brushes in quadrature. In order to simplify the figure, the frame is not shown and the assumption is made that the brushes have ideal commutation characteristics. Location of windings is shown for the pure amplidyne generator with (figure 1*b*) and without (figure 1*a*) a quadrature shunt and series winding. Figure 1*b* also illustrates the position of a few of the auxiliary windings used in amplidyne generators.

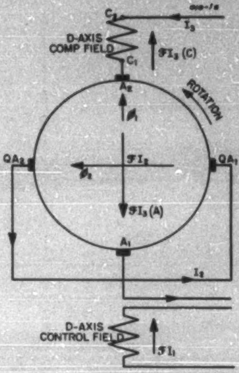

Figure 1a. Location and phase relation of windings of a pure amplidyne generator (two poles)

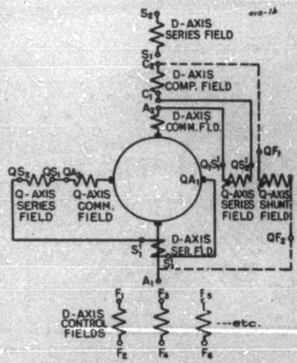

Figure 1b. Location and nomenclature of additional windings for a two-pole amplidyne generator

A flow of current I_1, produced by voltage E_1 in the direct-axis field F_1F_2 creates a direct-axis flux ϕ_1 in the first stage of amplification. The rotation of the armature develops a speed voltage E_2 and current I_2 in the short-circuit axis, QA_1, QA_2. As a result, the flow of armature current I_2 develops a distributed magnetomotive force $\mathcal{F}I_2$ and flux ϕ_2 in the quadrature axis. Rotation of the armature in this field then develops a speed voltage E_3 and load current I_3 in the output circuit.

Paper 40-10, recommended by the AIEE committee on industrial power applications, and presented at the AIEE winter convention, New York, N. Y., January 22-26, 1940. Manuscript submitted November 8, 1939; made available for preprinting December 7, 1939; released for final publication March 21, 1940.

---

cycles per second. This is likely to be a frequency which is representative of the control function for which the system is to be used, and it has been found that in such cases the electromechanical resonance is apt to be a very real problem, which must be foreseen in the design. In such cases it is found to be desirable to make the inductance of both generator and motor as low as possible by distributed compensating windings at the same time as the mechanical inertia is kept as low as possible. Both these factors tend to place the electromechanical resonance frequency above the frequency of the control functions, thus avoiding any tendency to mechanical oscillations.

When a control system is desired which demands a still higher ratio of amplification than is attainable in a single dynamoelectric amplifier it is possible to introduce a first stage of electron tubes of the type used in radio sets. Such tubes are adapted to an output sufficient to control an amplidyne whereas the primary control energy of such tubes is measured in microwatts. We have thus established simple means for industrial purposes to amplify a minute energy such as a beam of light into a quick and accurate control of power flow of many horsepowers. It is hoped that this will open up many new possibilities in the control of industrial processes.

Other aspects of the dynamoelectric amplifier are discussed in a paper by A. Fisher, dealing with machine design (pages 939-44) and a paper by D. R. Shoults, M. A. Edwards, and F. E. Crever, dealing with practical applications (pages 944-9).

Discussion

For discussion, see page 1136.

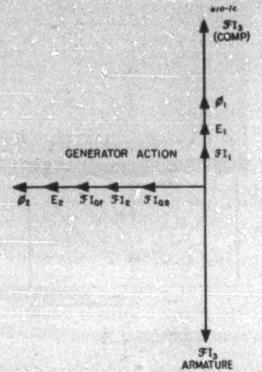

Figure 1c. Space vector relation of magnetomotive forces for a two-pole amplidyne generator

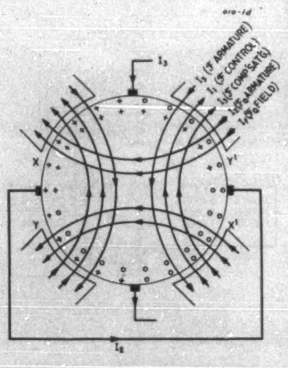

Figure 1d. Magnetomotive-force paths and armature-current distribution—two-pole amplidyne generator

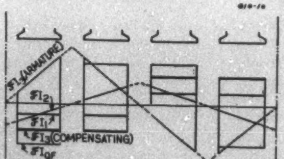

Figure 1e. Air-gap magnetomotive force distribution—two-pole amplidyne generator (not to scale)

The compensating-winding (C_1C_2) direct-axis magnetomotive force $\mathfrak{F}I_3(C)$ is in direct opposition to the effective armature magnetomotive force $\mathfrak{F}I_3(A)$ both in value and in direction. The complete neutralization of armature magnetomotive forces in the direct axis allows independent action of control magnetomotive force created by current I_1 in the first stage of amplification. The value of control flux ϕ_1 therefore need be only sufficient to overcome the electrical resistance drop in the short-circuit armature axis and as will be shown later, the reactance voltage drop during transients. The magnetomotive force $\mathfrak{F}I_1$ is equal to the ampere turns required to force the small flux ϕ_1 across the air gap and through the magnetic structure of the machine and is therefore relatively quite low.

In the second stage of amplification the magnetomotive force I_2 necessary to establish secondary flux ϕ_2 is equal to the ampere turns required to force ϕ_2 across the air gap and quadrature magnetic structure. The action in the second stage is similar to a salient-pole d-c dynamo with these exceptions: (1) the armature reaction is completely compensated preventing distortion; (2) air gaps are relatively smaller; (3) large magnetic sections prevent saturation; and (4) the armature winding, as a source of excitation, has low losses. As a result, power amplification in the second stage is higher than in a conventional machine. The addition of a self-excited quadrature winding QF_1, QF_2 (figure 1*b*) further reduces the quadrature current I_2 and increases the amplification considerably.

Magnetomotive forces are shown in space vector relation for both axes in figure 1*c* and the distribution for both the pole structure and air gap is shown in figures 1*d* and 1*e*. Current distribution for the armature circuit under load is shown in figure 1*d* where the outside conductors represent load current I_3 and the inside conductors quadrature current I_2. An unequal distribution of current in the armature is a result of current additions in XX^1 and subtractions in YY^1. This condition of unequal current distribution is improved by using quadrature shunt or series windings; however for most amplidyne generators, the essential action is not seriously affected by unequal current distribution.

There are no mutual linkages between the quadrature-axis windings and control windings in the direct axis. This essential feature plus others described previously, is responsible for the high speed of response. A change in control voltage E_1 produces a corresponding voltage change E_3 in the output circuit. A preliminary analysis has thus far shown an amplifier (1) with high amplification, (2) with a low mutual coupling, and (3) with a faithful pattern reproduction.

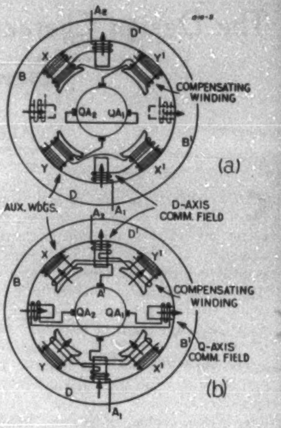

Figure 2. Schematic diagrams of two-pole amplidyne generators with block or concentrated compensation

The compensating windings are wound about each segmental pole in *a* and about each pair of poles in *b*

Practical Amplidynes

Figures 2*a* and 2*b* are schematic diagrams of practical amplidyne generators using block or concentrated compensation and excitation. The field structure is a four-segmental pole design with interpolar spaces sufficient for good commutation and low leakage. Paths are drawn for the direct, quadrature, and commutating pole fluxes. Field-frame section BB^1 carrying direct flux ϕ_1 may have less section than DD^1 which carries the higher quadrature main flux ϕ_2. In order to improve transient performance, reduce residual magnetism, and insure greater uniformity in design, a laminated frame is used.

In figure 2 the compensating winding is concentrated around each segmental pole. The ampere turns on the commutating pole are equal to the armature reaction plus sufficient overcompensation to reverse the armature coils undergoing commutation.

In figure 2*a* the compensating winding C_1C_2 is wound about a pair of segmental poles. The ampere turns on the compensating winding now add directly to the commutating-pole ampere turns, thus reducing the number of turns required on the commutating-pole body. Commutating poles, when used in the quadrature axis are connected as shown in figure 2*b*. The actual design connection used depends on the size of machine, available room for commutating poles, and required output characteristics.

The distribution of magnetomotive forces is shown in figure 1*c* for the essential direct and quadrature fields. In practice, the resultant distribution depends on the relative value of each component and is further influenced by commutation, commutating pole, and leakage magnetomotive forces. A plot of magnetomotive force around the armature circumference determines the value, location, and effectiveness of both first- and second-stage windings.

Steady-State Characteristics

In figure 3 the saturation curve of the direct and quadrature axis is shown. When the small direct-axis flux ϕ_1 is applied to the quadrature axis saturation curve at its operating point ϕ_2 and $\mathfrak{F}_2$ its magnetomotive force aids in one pole and subtracts unequally in the other as shown by X and Y, requiring more ampere turns than indicated by $\mathfrak{F}_1$. The value of $\mathfrak{F}_1$ is actually greater than the calculated value because of (1) local distortion in the pole face and armature slots, (2) reactive ampere turns of coils undergoing commutation, (3) imperfect compensation, and (4) increased effective armature resistance due to changes in brush contact drop. These secondary effects, however, are relatively small in the normal range of operation.

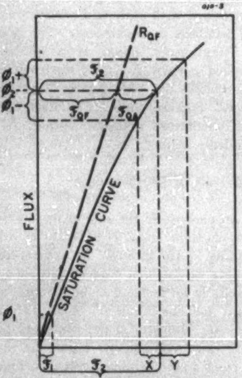

Figure 3. Saturation curves of first and second stages

The second-stage saturation curve is practically identical with first stage. The quadrature field resistance line is R_{QF} and its magnetomotive force is $\mathfrak{F}_{QF}$

Since ϕ_1 is so much smaller than ϕ_2 there is practically no distortion introduced by ϕ_1. An interesting and important feature of design is that all of the armature leakage flux connected with ϕ_2 is useful in producing output voltage E_3. This leakage flux, being air borne, relieves the iron magnetic circuits, effectively reduces the size of the machine, increases amplification, and, having zero coupling with other windings, aids in speeding up the response.

Figure 3 also illustrates the advantage of using a shunt quadrature field QF_1, QF_2. The strength of this quadrature field is adjusted so that its resistance line R_{QF} does not intersect the quadrature-axis saturation curve. The amplification is increased approximately, as follows: (where A_F is the new amplification and A_A the original amplification):

$$A_F=\frac{(\mathfrak{F}_2)^2}{(\mathfrak{F}_{QA})^2}\times A_A$$

Quadrature armature current is reduced in the ratio of $\mathfrak{F}_2$ to $\mathfrak{F}_{QA}$ relieving the armature circuit and resulting in a more uniform balance of armature currents. In order to reduce the effect of mutual coupling between the quadrature-armature and shunt-field windings, a high inductance, entirely separate from the machine, is normally connected in series with the shunt winding, effectively reducing interference during transients.

Commutation

Good commutation is essential for high amplification and good stability. Well-defined neutrals and linear commutation reduce the magnetizing and demagnetizing magnetomotive forces, due to over or undercompensated armature coils, undergoing commutation. It is sometimes desirable to use additional commutating poles in the quadrature axis QA_1, QA_2, even at the expense of increased resistance and inductance, on account of the more perfectly defined neutrals and decreased cross magnetization obtainable.

Amplidyne generators have been built with and without commutating poles depending on commutation factors and sensitivity requirements of design. Interpolar commutating zones are designed as in conventional machines; secondary current I_2 and output currents I_3 are commutated independently by either brush resistance drop or with the aid of commutating-pole flux. As a coil in the direct-axis undergoes commutation, and changes its direction of I_3 current flow, quadrature current I_2 flows through the same coil, without a change of direction. As a result there is a slight distortion of flux across the commutating-pole face but otherwise commutation is not affected. When commutating poles are not used, a slight distortion of current distribution is found across the brush face. Similar effects appear in the quadrature axis as I_2 undergoes commutation. Experience shows that each current can be commutated independently.

Output Characteristics

The general characteristics of a four-kw amplidyne generator are shown in figure 4. Although the transient response with a quadrature shunt field is slower than without such a field, its speed approaches the pure amplidyne generator when external reactance is added to the quadrature field. It has the decided advantage

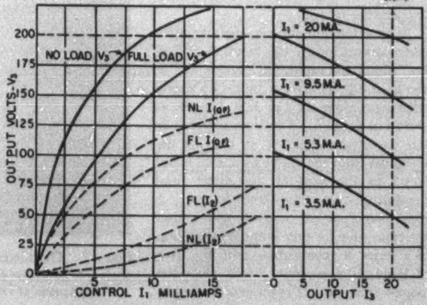

Figure 4. Characteristics of a four-kw amplidyne generator with a quadrature shunt field QF. (Actual field and short-circuit current values are omitted)

of low excitation and high amplification and is used extensively. At full rating the amplification for a given field setting is 18,000 and at three-fourths voltage and current 100,000, increasing to higher values at lower voltages.

Transient Performance

Under conditions of transient performance the current build-up in the first stage with a sudden applied voltage E_1 is:

$$i_1=\frac{E_1}{R_1}\left(1-\epsilon^{\frac{-R_1t_1}{L_1}}\right)$$

neglecting eddy current losses and saturation i_1 and ϕ_1 are proportional to each other and are in time phase. Inductance L_1 varies with the degree of saturation and when appreciable saturation is obtained, a step-by-step method of solution can be used.

The expression for current build-up in the second stage with a sudden application of load is:

$$i_2=\frac{E_2}{R_2}\left(1-\epsilon^{\frac{-R_2t_2}{L_2}}\right)$$

Voltage e_2 in the second stage begins its build-up at the same instant as i_1, in the first stage and the equation for voltage and current in this stage is:

$$e_2=ki_1=R_2i_2+L_2\frac{di_2}{dt_2}$$

A solution of equations of this type is:

$$i_2=\frac{E_1K}{R_1R_2}\left[1-\frac{\epsilon^{\frac{-R_1t_1}{L_1}}}{\left(1-\frac{L_2R_1}{L_1R_2}\right)}+\frac{\epsilon^{\frac{-R_2t_2}{L_2}}}{\left(\frac{L_1R_2}{L_2R_1}-1\right)}\right]$$

or in more general terms:

$$\text{load volts}=\left(E_3-B\epsilon^{\frac{-R_1t_1}{L_1}}+C\epsilon^{\frac{-R_2t_2}{L_2}}\right)$$

where B and C are constants depending on L and R.

Figure 5 is a graphical picture of these exponential terms.

In an actual amplidyne generator, with eddy-current losses, the fluxes ϕ_1 and ϕ_2 lag behind the excitation current and so the load voltage always builds up slowly with zero slope at the first instant as shown in figure 5. The time constant in the two-stage amplifier, as may be determined from the above formulas, is not equal to the sum of the direct- and quadrature-axes time components. A rigid mathematical analysis shows that the expression for time is equal to the sum of a series of exponentials with the time of build-up somewhat longer than the longest time lag. It is therefore essential in design to minimize the component having the longest time lag.

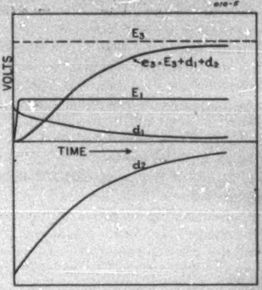

Figure 5. Transient response with sudden application of voltage E_1, on first stage

E_3 is output voltage

Test Performance

The oscillograms shown in figures 6 and 7 show the transient response of a four-kw amplidyne generator when control current or voltage is suddenly applied. Under the test conditions no quadrature shunt field and no overexcitation were used and amplification was approximately 6,000.

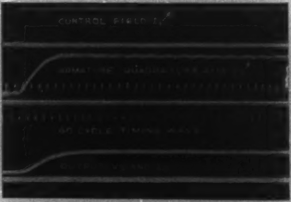

Figure 6. Oscillogram of transient response of a four-kw amplidyne generator with a sudden application of current I_1 in first stage

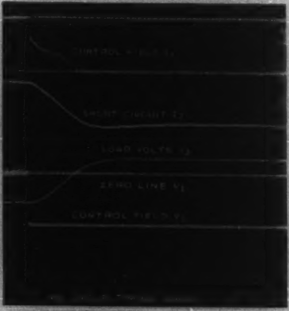

Figure 7. Oscillogram of transient response of a four-kw amplidyne generator with a sudden application of voltage in first stage

Figure 8. Oscillogram in transformer response with a sudden application of current in first stage of a four-kw amplidyne generator

Showing effect of eddy current and iron losses on a blocked armature with brushes raised

Figure 8 is an oscillogram of the same amplidyne with a blocked armature and all windings open-circuited. The delay in transformer action of a suddenly applied current I_1 shows the time lag introduced by eddy-current and iron losses. Similar results are obtained when the quadrature armature current I_2 is suddenly applied.

Analysis of Performance

An analysis of the rate of response or amplification alone, is likely to be misleading. An increase in control-field copper weight or a reduction in air gap results in an increase of both time constant and amplification. A longer time constant indicates slower response, but with equal volt-amperes input, the time to reach a predetermined voltage is much less for a given amplidyne generator with

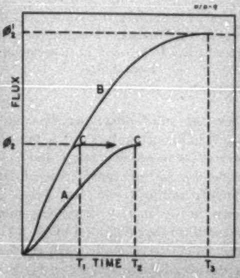

Figure 9. Transient performance showing effect of time constant and amplification

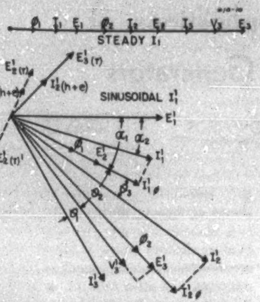

Figure 10. Vector diagram of a pure amplidyne generator with constant and sinusoidal excitation

Speed voltages are in phase with fluxes $I_1^1\phi$, $I_2^1\phi$, $I_1(h+e)$ $I_2(h+e)$ are vector components of I_1^1 and I_2^1

the higher time constant and amplification. The time T_1 to reach ϕ_2 in figure 9 is less for characteristic *B* than T_2 is for *A*, although the time T_3 to reach the ultimate flux level is longer on characteristic *B* than for *A*.

The amplidyne generator lends itself to field forcing on account of low control watts. Field forcing on curve *B* with the control circuit cutting off at point C^1 is good practice. In judging oscillograms as shown in this paper and in comparing operation with other amplifiers, comparison must be made on the basis of volt-amperes input. A long time for build-up usually indicates a high amplification.

Amplification

Amplification has been defined as the ratio of volt-amperes output to volt-amperes input. With steady d-c control current I_1 the vector diagram is a straight line as shown in figure 10, and

$$A=\frac{V_3I_3}{E_2I_2}\times\frac{E_2I_2}{E_1I_1}=\frac{V_3I_3}{E_1I_1}$$

for an amplidyne generator without a quadrature shunt field. Amplification characteristics of a four-kw machine less quadrature shunt field are shown in figure 11. Amplifications from 2,000 to 10,000 and higher at full load are practical depending on the rating obtained from a given frame size. First-stage amplification is much higher than second stage and for example, at full load and normal saturation, second-stage amplification is about 40 for a four-kw machine.

Performance characteristics of an amplidyne generator are judged by the ability to follow sinusoidal voltage of low frequency applied to the control field. There is a reduction in amplification caused by the power-factor angle of the load and armature quadrature axis and a further reduction caused by the angular lag between magnetomotive force and flux, a result of eddy current, hysteresis, and secondary losses of commutation. The new low-frequency amplification factor is:

$$A'=\frac{V_3'I_3'}{E_1'I_1'}$$

The vector diagram is shown in figure 10 for sinusoidal field excitation and the angular lags in both stages are shown for both inductance lag and flux losses. Angular displacements have been exaggerated for clarity. Total amplification is:

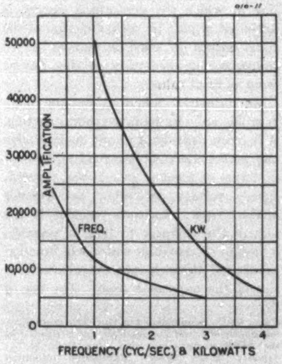

Figure 11. Relation of amplification with load and first-stage frequency on a four-kw amplidyne generator

Frequency curve plotted for partial load initial setting of $A=30{,}000$

$$A_{31}=\frac{V_3'I_3'}{E_1'I_1'}=\frac{V_3I_3\cos\theta_1\cos^2\theta_2\cos^2\alpha_1}{E_1I_1\cos\alpha_2}$$

A change in ϕ_1 in the first stage induces transformer voltage E_T' across A_1A_2 which is completely cancelled by voltage E_T' produced by compensating winding C_1C_2 with 100 per cent coupling. Speed voltage E_2' in phase with ϕ_1 across brushes QA_1, QA_2 generates short-circuit current I_2', which magnetomotive force creates quadrature flux ϕ_2. Output speed voltage E_3' in phase with ϕ_2 is generated across main brushes A_1A_2. The transformer effect produced by ϕ_2 appears as additional eddy current and hysteresis losses $I_2'(h+e)$ but no transformer voltage is induced across the output circuit.

A lag between excitation and flux in both stages is shown on the vector diagram, as a result of hysteresis and eddy-current losses. The sine-wave resultant of $I(h+e)$ is used on the diagram and illustrates the reduction in amplification as shown by an increase in angular lag. The curve in figure 11 indicates how amplification changes with frequency for this particular four-kw amplidyne generator. The change with frequency depends on the change in ratio of resistance to inductance and on the change of hysteresis and eddy-current losses with frequency. Inductance is the controlling factor since its value is usually greater than resistance.

General Discussion

The diagrams and formulas indicate the design features necessary for the construction of amplidyne generators for good transient performance. Amplification is increased by reducing the angular lag between the various vectors. The use of low-reactance armatures and more complete compensation of armature reaction effectively reduces the angular lag. Effective compensation also prevents regenerative back coupling of transformer voltages and over- and under-compensation during steady-state conditions. Amplification is further increased by reducing the transient losses produced by commutation currents, and variable brush-contact drops.

Normal requirements of design such as low iron losses, low magnetic distortions, and low magnetic densities favor the use of small air gaps, and therefore high amplifications. The output of an amplidyne generator is somewhat less than a conventional generator of the same frame size on account of the lower den-

Figure 12. Oscillogram of angular lag between stages of a four-kw amplidyne generator with approximately two-cycle excitation

sities used. However the efficiency is usually higher than a conventional machine, since the losses are less.

Many additional windings are used to obtain different characteristics. A series winding QS_1, QS_2, in the short-circuit axis creates a more uniform distribution of magnetomotive force across the pole faces, results in lower short-circuit current I_2, and less current distortion in the armature but has the disadvantage of increased impedance and ineffective use of leakage flux. Increased amplification is also obtained by using this field, reducing the total losses in the second stage. A series winding $S_1{}^1S_2{}^1$ is sometimes used to compensate for changes in brush-contact resistance and results in higher amplification.

Greatly increased amplification is obtained by overcompensating winding C_1C_2 slightly. The result is in general similar to the addition of a series winding in a conventional d-c generator and the amplidyne generator will tend to self-excite. This higher steady-state amplification is obtained at the expense of transient or low-frequency amplification, in which the back-coupling effect is increased. There are conditions where over- or undercompensation is desirable but the use of such windings for obtaining particular characteristics depends on the application. In general the performance is judged by response to transient or low-frequency excitations, and the standards for amplification should be based at a representative frequency.

Conclusions

The design features and performance curves that have been discussed indicate the remarkable range and fidelity of amplification that can be secured in the practical design of this new type of d-c machine designated as the amplidyne generator. The transient performance, which is the real test of an amplidyne generator, indicates that the problems met with in designs giving high amplification, speed of response, and stability have been solved successfully. In view of these results, it seems probable that this type of machine will have many useful applications in the automatic control of industrial operations.

Industrial Applications of Amplidyne Generators

D. R. SHOULTS

F. E. CREVER
ASSOCIATE AIEE

A CONSIDERABLE number of "amplidyne"* generators[1,2] have been applied in conjunction with other electrical apparatus to industrial processes within the past few months. A summary of these applications indicates that the amplidyne generators are of particular value in conjunction with so-called "closed-cycle" control systems. A closed-cycle system may be defined as one in which the controlling agency is actuated in part by some function of the final output in such a manner as to minimize any deviation of this output from an ideal value.

As industrial functions become more complex and requirements more exacting, it is often desirable to limit or determine the performance of electrical equipment in terms of torque, horsepower, current, speed, voltage, or other performance characteristic. In such cases it is the aim of the engineer to find, if possible, a system of machines which will function as desired through inherent characteristics of the apparatus used. The use of the three-field d-c generator in electric-shovel equipment illustrates the utilization of basic machine characteristics to produce definite forces or torques which are more or less independent of the load reactions. In other difficult applications it is often more feasible to apply closed-cycle controllers, making use of more standard power apparatus and so modifying the power flow to the apparatus as to produce the required results.

Closed-Cycle Controllers

In designing a closed-cycle controller of this sort, there are four factors which must be considered:

First, there must be some standard of performance established and a mechanical or electrical counterpart determined. This may be, for example, the torque or force of a spring, a voltage, a current, or a combination of these.

Second, the functioning of the complete equipment must be expressed in a similar physical manner. Thus the speed of a motor may be expressed by means of the frequency or voltage of a tachometer generator driven by the motor. The torque of a separately excited d-c motor may be determined by the current flowing through its armature. Such indication of performance is then "fed back" to the indication of ideal performance in such a manner as to obtain as a physical quantity, the difference between the ideal and actual indicators so as to determine the departure of the actual from the ideal operation.

Paper 40-23, recommended by the AIEE committee on industrial power applications, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 8, 1939; made available for preprinting December 19, 1939; released for final publication March 21, 1940.

[1] For all numbered references, see list at end of paper.

* A convenient name selected to designate a dynamoelectric amplifier, which it is hoped will be generally adopted.

The third requirement is then that this difference, representing a deviation from the desired value, shall be used to modify or control the operation to reduce the deviation. With power apparatus of usual size, it is necessary to amplify this physical quantity in order that it may be used to produce the required correction.

The fourth factor, that of stability, is one which must be examined very carefully in any closed-cycle controller. A complete discussion of this problem of stability of a closed-cycle system such as a servo mechanism, electrical regulator, or similar controller is beyond the scope of this paper, but a discussion of the important factors is desirable here. The cause of most instability of such systems is the time lag which occurs in various parts of the system between the indication of error and the output. Some time lag is inevitable in any amplifying device of which we have knowledge, as even radio-type amplifiers have limiting frequencies above which they cannot function effectively.

The speed of response of a control system is usually determined by the element having the longest time delay and the stability problem becomes most serious where two or more sequential parts of the system have time-delay factors of similar magnitude. In the usual industrial power apparatus, the response time of the final controlled element is appreciable. This may be the time delay of a large generator field, the acceleration of a motor with a large connected inertia, or similar action. In this case, then, it is important in the closed-cycle system of control to shorten the response times of all the elements of the system prior to the final one, that is, any primary or secondary amplifier should function with much less time lag than that of the final power device.

Amplifier Requirements

An amplifier used in a closed-cycle control or regulating system should, therefore, function with a minimum time lag between input signals and output. In most industrial systems, the threshold value of time lag above which difficulty may be expected is in the neighborhood of one-tenth to one-quarter second. Contradictory examples can, of course, be found but the foregoing is a reasonable general value.

The next factor to be considered is the magnitude of the amplification. If the final unit to be controlled is the field of a large generator or motor, the power output required may be from a fraction of a kilowatt to many kilowatts. The differential power obtained from the feedback comparison is usually limited, being at the most a few watts and at times materially less than this where high accuracy is a factor. The amplifier must then cover its full output range with this excitation change.

A uniform or linear relationship between output and input signals may be an important factor in obtaining sensitive yet stable operation. There are exceptions here also where, for instance, an equal percentage response should be obtained at all times, or where some other relationship is desirable. In the usual case it is found expedient to provide any required nonlinear variations by special means used in conjunction with linear amplifiers.

The last, but by no means the least important consideration in designing or selecting the amplifier, is that it have a high degree of reliability and that it be sufficiently elemental in operation that it may be understood by nontechnical maintenance personnel. Shutdown or loss of production time in practically any industrial process is a costly thing, but in some processes this is vitally so. Such continuous processes as steel or paper making if unexpectedly interrupted may incur a loss in product alone of greater value than the first cost of the device causing the failure. In processes such as glass making, stoppage of some parts may require weeks or even months to restart.

In any case, any failure to function successfully should only be the result of the failure of some part or device which will be readily and quickly apparent to the maintenance electrician. Furthermore, the approach of such a failure should be determinable by routine inspection of the apparatus involved.

The Amplidyne Generator

The amplidyne generator meets the foregoing requirements in most instances to a very complete degree. The response time as determined previously,[3] is sufficiently short so that the over-all time lag of typical control systems is not increased materially by the use of this amplifier. The amplification constant is sufficiently high that in many cases the amplidyne generator can be used directly without supplementary amplifiers. Where the requirements of high accuracy dictate, it is readily controllable by sensitive high-accuracy amplifiers of low power output. The required input signal for the amplidyne generator is usually of the magnitude of a watt or so, which may be easily obtained from even a vacuum-tube amplifier using commercial radio-receiving tubes.

The amplidyne generator, while of somewhat unusual arrangement, utilizes the physical parts and method of construction of the familiar d-c machinery and consequently, may be readily tested for grounds, short circuits, or other causes of misoperation by readily available testing apparatus.

Methods of Use

There are three more or less basic manners in which the amplidyne generators may be employed in closed-cycle controllers. These differ in the means by which the excitation power or control signal is obtained and applied to the amplidyne generator field.

In the first and simplest method as illustrated in figure 1, the amplidyne exciter is equipped with two balanced fields on the control axis. One of these fields is excited from a source which provides the primary standard of performance. The excitation power supplied from this source is many times that required to obtain full output from the amplidyne generator. The second field is excited from the output function of the apparatus, which in figure 1 is the line current of a d-c generator, but may be alternatively speed, voltage, position, or other characteristic such that the control-field current will be proportional to this final function. This excitation,

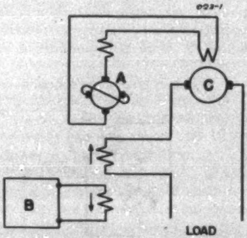

Figure 1. Circuit arrangement of an amplidyne exciter, used in a closed control system, excited by balanced field action

A—Amplidyne exciter with compensating field and opposed control fields

B—Any suitable primary current source

C—Separately excited d-c generator, controlled to deliver current, proportional to that of primary source differential with respect to the primary excitation, is also many times that required to excite the amplidyne generator. The net difference of these two exciting components then produces such excitation as may be required for the control range required. Inasmuch as the amplidyne generators operate at low flux densities on the control axis, there is adequate room in interpolar space for opposing field circuits of the magnitude described. Additional fields may be placed on this axis to assist in stabilization or to provide secondary control influences.

The limit of sensitivity of the amplidyne control systems using this arrangement is determined by the maximum values of opposed excitation which may be obtained from the two sources and placed upon the amplidyne control axis. This accuracy, in general, is in the neighborhood of a few per cent and is suitable for a great number of uses where speed of response and reliability are of more concern than accuracy.

The second method of obtaining the amplidyne generator excitation is from differential voltage circuits as illustrated in figure 2. Here the standard of comparison and the indication of output performance are expressed as opposed voltages with their circuits interconnected through the field circuit of the amplidyne generator. Any deviation of output from the ideal results in a difference in voltage, with a current flow of equivalent direction and magnitude through the amplidyne generator field so as to produce a change in output to reduce the deviation. Where sufficient control power is available so that the sources of control voltage are influenced to only a minor degree by the amplidyne field current, this is an effective means of control. Its accuracy is limited by the power available from the two voltage sources only and in some cases may be made extremely high. The disadvantage of this circuit arrangement is that it requires an electrical interconnection between the two sources of comparison. This, at times, may be impractical.

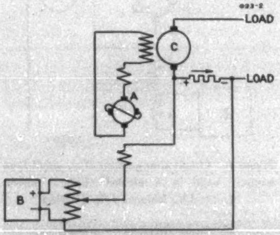

Figure 2. Circuit arrangement of an amplidyne exciter, used in a closed control system, excited from a differential voltage source

A—Amplidyne exciter with compensating and control fields

B—Any suitable primary source of direct voltage

C—Separately excited d-c generator controlled to deliver current proportional to the voltage of the primary source

A third method of application of the amplidyne equipment is through the use of supplementary composing amplifiers as illustrated in figure 3. The composing amplifier output used to excite the amplidyne generator is arranged in accordance with any desired relation of control functions. With such an amplifier, it is possible, for example, to control voltage of a generator accurately within certain load limits and at these load limits to transfer from voltage to current limit control or vice versa, depending upon the operating conditions. The amplidyne generator in this case functions as an intermediate power amplifier and as such, its characteristics of low time lag and linearity of characteristics are usually most important.

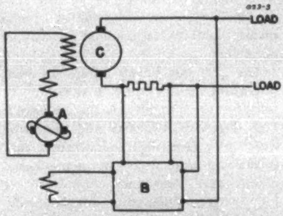

Figure 3. Circuit arrangement of an amplidyne exciter used in a closed control system, excited by composing amplifier

A—Amplidyne exciter with compensating and control fields

B—Composing amplifier combining current and voltage of d-c generator in required relationship with suitable standards to provide the amplidyne excitation

C—Separately excited d-c generator controlled to operate with a specified current-voltage relationship

Some of the typical applications of amplidyne generators which have been made recently will be briefly described. A complete discussion of all of the engineering features of each application is impractical and, accordingly, this summary will be indicative mainly of the variety of uses to which these machines may be put.

Machine-Tool Control

A simple yet interesting application of amplidyne equipment is in connection with a multiple-head boring mill in the Schenectady works of the General Electric Company. The two motions on each head of the mill (figure 4) are controlled by suitable motor-operated lead screws. The control motor for each head is arranged with a double-throw mechanical clutch mechanism so that it may operate either lead screw.

The operator may preset the next cut to be made by means of dials registering feet, inches, and thousandths of inches. When one cut is finished it is only necessary to clutch in the motor to the proper motion, press a button, and the equipment will automatically move the cutting tool to the exact position for the next cut.

This positioning control is obtained by a series of limit switches and accurate mechanical means of operating these from the motion of the heads. Each d-c control motor is separately excited and

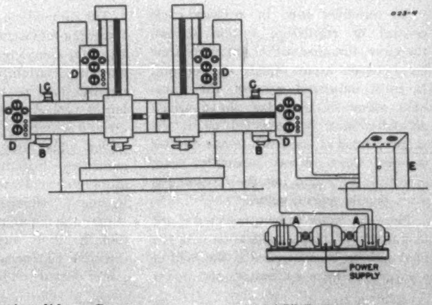

Figure 4. Schematic arrangement of amplidyne control equipment for automatic positioning of cutting heads on a boring mill

A—Amplidyne generators

B—Control motors

D—Dial indicators and limit switches

E—Main control cabinet

receives its armature power from an amplidyne generator. The field excitation of the amplidyne generator is applied through circuits controlled by the precision limit switches. The amplidyne equipment by its low control power requirement permits these switches to be small in size and hence accurate in performance. One other important point is that the speed of the control motor is definitely held at any set value by means of the amplidyne equipment which is excited from a voltage-matching circuit. This circuit consists of a pilot generator, driven from the control motor, and a potentiometer circuit across the excitation source. When the slowdown limit switch is reached the motor is slowed down to $^1/_{50}$ rated speed by a change in potentiometer connection. This slow speed is held accurately regardless of the friction conditions which are encountered, thus permitting of accurate positioning on the final limit switch. Figure 5 illustrates schematically the control circuits for one of the control motors. Switches *A*, *B*, and *C* are the limit switches operated respectively by the foot, inch, and thousandths limit switches. After movement is started by pressing one of the directional push-button stations, switches *A* and *B* are opened as the final position nears, and the equipment slows down to an accurately held approach speed. At the final point, switch *C* opens which deenergizes the equipment, bringing about a quick and accurate stop.

Reel Control

The problem of reeling a continuous strip of material is common to many industrial processes. The material may be delivered at constant speed or at times the speed of the material may be varied through wide limits. In many cases the drive requirements of the main part of the machine may be such that adjustable generator-voltage control is used for acceleration and to control the speed. In this case the speed of the strip may be directly proportional to the voltage applied to the driving system. In such cases, the requirements of constant reeling tension may be met by controlling an adjustable-speed d-c motor driving the reel core in such a manner that it will draw constant armature current from the adjustable-voltage power supply. The use of an amplidyne exciter for the reel motor, arranged so as to vary the excitation to cause the motor to draw a constant adjusted value of current has been successful in the reeling of steel strip as it is delivered from a tandem cold-strip mill.

In some installations other factors, besides the steady-state torque delivered to supply the strip tension, may become important. On drives requiring threading at low speed with subsequent rapid acceleration to operating speed, the acceleration torque of the motor and reel may be a substantial proportion of the total torque delivered and consequently must be taken into account. It is also sometimes desirable to provide for accurate speed control of the unloaded reel motor prior to the time the strip reaches the reel and to provide an automatic transition from speed control to tension control as the strip is threaded into the reel and the reel diameter begins to build up. Such operations as these may be obtained through the use of amplidyne equipment together with a supplementary composing amplifier or circuit. The reel shown in figure 6 was controlled by amplidyne equipment using one unit as a composing amplifier to combine the speed and acceleration control functions with a second and larger amplidyne exciter combining these functions with the main one of strip tension control in exciting the reel motor.

Steel-Strip Polisher

Several installations of a somewhat similar nature to the one just described have been made to control strip-polishing machines. These strip-polishing machines consist essentially of unwinding and winding reels, arranged in such a manner that the steel strip may be wound from one to the other and back again. The strip is buffed or polished by suitable means as it passes between the two reels. The drive must maintain substantially constant tension in the strip between the two reels and should also maintain uniform strip speed as the diameter of one reel decreases and the other increases. Amplidyne excitation control has been successfully applied to several of these machines to provide the desired characteristics of tension and speed. Figure 7 shows the general setup of such a machine with the two reels and the polishing mechanism. The motor generator set supplying power to the two reel motors, with the amplidyne generator used for excitation control, is shown in the left background.

Figure 6. Hot-strip-mill installation using amplidyne exciter for constant tension control of strip tension at reel

Figure 7. Steel-strip polishing apparatus using amplidyne exciter for reel motors to control speed and tension

Single-Motor Paper-Machine Drive

Accurate control of the speed of a paper-making machine is highly desirable to assure a uniform product and a minimum of waste. A wide range of operating speeds is also desirable so that both light and heavy grades of paper may be made on the same machine. Figure 8 shows the schematic arrangement of an amplidyne exciter applied to such a machine where the main drive motor was controlled by adjustable generator voltage. The amplidyne exciter controls the main-generator field excitation in response to a signal indication obtained from a tube-type composing amplifier. The indication of speed is supplied by a pilot generator of the permanent-magnet type which is driven from the line shaft of the machine. The voltage of this pilot generator, or a portion of it, is balanced against a voltage standard in the composing amplifier. The difference controls the amplidyne excitation to maintain the proper speed.

In addition to the main requirement of speed control, the current is held within definite limits during acceleration or retardation, figure 9. In starting the drive, the line contactor is closed and the current rises immediately to the limiting value slightly above full load. The drive accelerates at this current limit until the set speed is reached where the current drops to the normal steady-state value required by the load. When a change in speed is required, the operator moves the pilot-generator calibrating rheostat. Should this require an increase in speed, the current will be held at the upper current limit until the new speed is reached. Should the change be a decrease, the current will decrease to the point where the reverse-current limit control becomes effective. The drive will then slow down until the new speed is reached where the current will again stabilize at that required for the load.

The over-all amplification of the control system is very high and the speed is accurately held to a fraction of one per cent. The current limits are not critical and are held within a few per cent.

Such a system of control is applicable in many places, particularly where the inertia of the mechanical system is large and a considerable time is required to accelerate from one speed to another.

Flying-Shear Control

The problem of acceleration control is also encountered in the application of motors to a flying shear at the end of a hot strip mill. Two successful amplidyne exciter applications have been made for this service. The shear is driven by a d-c motor with adjustable generator voltage supply. Synchronization of speed of shear with that of the last mill stand is provided by a supplementary mechanical interconnection including an overrunning clutch. The clutch permits the shear to be stopped while the mill is in operation.

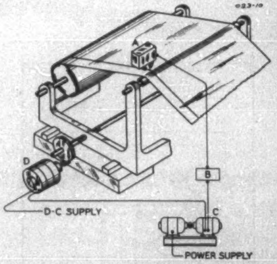

Figure 10. Photoelectric register equipment using amplidyne generator for power supply to servo correcting motor

A—Scanning head
B—Electronic amplifier
C—Amplidyne generator
D—Control motor

As the leading end of the strip approaches the shear, the shear is accelerated rapidly until the clutch engages and thereafter the motor exerts just sufficient torque to maintain the clutch in engagement under all normal load conditions. The shear must be quickly and accurately accelerated in such a manner that the first cut will be made just as the end of the strip comes to the shear. A high rate of acceleration is required and is limited only by the commutating capacity of the electrical equipment. As the shear reaches the speed corresponding to the mill speed, at which time the speed is limited by the overrunning clutch, the torque must be reduced to a much lower value just sufficient to maintain contact in the

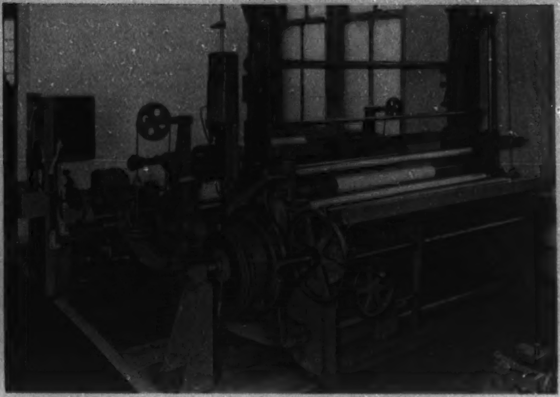

Figure 11. Installation of amplidyne unit on photoelectrically controlled winder and slitter

clutch. Thus, we have the problem of two degrees of current control, the transition from one to the other occurring at a certain definite speed relationship as determined by the relative voltages of two tachometer generators, one driven from the last mill stand and the other from the shear. The amplidyne exciter is particularly useful in this arrangement as the speed of response of the entire system must be high to prevent lagging or overshooting in torque on the speedy acceleration, with rapid transition to a lower torque as the clutch engages.

Photoelectric Side Register Control

A number of amplidyne generators have been built to deliver power to motors holding registration of a web of paper being rewound and slit as illustrated in figure 10. A photoelectric scanning head and amplifier obtains an indication from the edge of the web or from a line printed on the web of paper to determine when the web deviates from its proper position. The indication is amplified and applied to the field of the amplidyne generator. This generator applies power to a separate-excited d-c motor which is arranged to shift the main roll of paper sideways to bring about a correction in registration. Arrangements are made so that the paper is moved beneath the scanning point simultaneous with the moving of the main paper roll in order to eliminate any tendency to hunt which would be caused by a lag in the movement of the paper in front of the scanning head after the main paper roll has been moved.

An accuracy of approximately 0.01 inch is required in controlling the edge of the paper or line on the paper. When winding at high speed, the paper may be found to deviate rapidly from a set position so that a correcting speed of from 30 to 60 inches per minute is required to keep up with the errors introduced in the paper. Thus, at times the control line may move the full width of the accuracy zone in only $^1/_{100}$ of a second. A high response rate of all the equipment involved is necessary to keep up with the errors, and particularly necessary in order to obtain stable operation without hunting with the combination of high accuracy and high speed of correction.

Synchronous-Motor Excitation Control

In a recent installation of a 5,000-horsepower synchronous-motor drive for a structural-steel mill the motor excitation was supplied by an amplidyne exciter. This was controlled in such a manner that the motor operated with substantially constant leading reactive kilovolt-amperes at all loads up to 150 per cent of normal. This control assists the synchronous motor to develop high pull-out torque when peak loads are encountered. The 50-kw amplidyne-exciter-control excitation was obtained as a function of motor current and line voltage. As this excitation requirement was of the order of a few watts it was obtained from potential and current transformer circuits without further amplification.

Conclusions

Amplidyne generators have been successfully applied in a considerable number of industrial processes. In addition to the uses previously mentioned they are controlling load division between large parallel-operating d-c motors; controlling reel tension in a wire-drawing machine; and maintaining close speed regulation of tandem cold strip mills. The field of application has expanded rapidly but there are still many other uses to which these machines may be profitably put.

Systems requiring a quickly reversible source of armature power or field excitation are particularly benefited by the excellent amplidyne performance. In fields where thyratron grid-controlled rectifiers have been used to obtain a quick response characteristic of power proportions, the amplidyne generator offers an alternative method of control which some users will prefer because of the physical nature of the equipment.

Thus the amplidyne generator offers considerable promise in industrial power applications where the use of dynamo-electric machines is desirable but where other types of power amplifiers have been required in order to obtain proper responsiveness of control.

I. Problem

RECENT experience with bridges for the determination of power factor and dielectric constant of small oil samples over a range of frequency has indicated the desirability of improving their characteristics. These improvements or developments have to do principally with changes in circuit arrangements, a generalized representation of the bridge network in terms of controllable impedances, an increased sensitivity inherent in the bridge itself, and an effective means for controlling the influence of inherent impedances extraneous to the bridge measuring arms on the accuracy, precision, and dependency of the bridge measurements and balances.

The foregoing has been developed in connection with a joint research project of the Utilities Co-ordinated Research, Inc. (Association of Edison Illuminating Companies) and the Massachusetts Institute of Technology on the electrical and chemical studies of the deterioration of electrical insulating oils. This work involves the determination of the change in power factor and dielectric constant of the oil as a function of

(*a*). Deterioration brought about by

1. Oxygen absorbed during oxidation
2. Heat with an inert gas
3. Materials in contact with the oil under service conditions in combination with (1) or (2)
4. Processes (1), (2), and (3) carried on with or without the presence of the volatile products of deterioration

(*b*). Chemical products formed under (*a*)

(*c*). Initial physical, chemical, electrical, and optical data characterizing the oil

The oils used in these studies include standard insulating oils, narrow cuts from different crudes prepared by distillation and solvent refining, the purpose being to obtain a complementary set of samples with wide variation in initial physical and chemical properties, and synthetic samples of known composition.

The foregoing studies require that power factor and dielectric constants be measured with relatively small samples since, for example, during oxidation it is necessary to make a number of electrical tests during the run in addition to a large group of chemical tests, and in the use of specially prepared samples of oil only limited quantities of the oil are practically available. Some work done on the oxidation of oils in which the volatile products are retained in part in the oil has indicated that more satisfactory electrical measurements may be made at relatively low voltage gradients. Furthermore, it was desired to make the electrical measurements over a range of frequency, for the present 10–20,000 cycles per second, to permit a more complete study of the nature of the loss. This again limits the applied bridge voltage to relatively low values. Thus we have a combination of factors, small measuring cell capacitances, low applied bridge voltages, and low frequencies each of which makes more difficult precise determinations of the power-factor and dielectric-constant measurements.

It is logical to inquire as to what would be considered a desirable precision of these measurements. The precision of the measurements is determined principally by (*a*) the precision of the bridge measurements, (*b*) the precision of the temperature measurement of the oil in the measuring cell, (*c*) the effect of cleaning procedure used in cleaning the measuring cell before the introduction of the oil, the nature of the measuring cell, and the method of introducing the sample into the measuring cell, and (*d*) the effect of time and change of temperature of the oil in the cell. The accuracy of any particular measurement is probably principally determined by (*c*) and the precision of the measurements for a change in frequency is principally determined by (*a*) and (*b*). The effect of temperature measurement of the sample under test may be determined by first considering an oil which doubles its power factor for any change in temperature of 15 degrees centigrade. To obtain an electrical measurement to plus or minus one per cent of the measurement requires the temperature measurement of the sample to ±0.21 degrees centigrade. Similarly for a value of 10 degrees instead of 15 degrees centigrade, a precision of electrical measurement of plus or minus one per cent of the measurement requires a temperature measurement of ± 0.14 degrees centigrade. In view of the foregoing it is believed that a precision of measurement of power factor to plus or minus one per cent of the power factor represents satisfactory measurements. Thus for an oil sample power factor of 10^{-4} (an approximate range for standard insulating oils at 25 degrees centigrade) the precision of power-factor measurement by the bridge must be $\pm 10^{-6}$ and for an oil sample power factor of 10^{-2} a measurement precision of $\pm 10^{-4}$.

For the case of capacitance or dielectric-constant measurements an accuracy of measurement of plus or minus one per cent is readily obtainable, this being principally determined by the accuracy of the measuring-arm resistances and the calibration of the reference capacitor. However, in the studies referred to in the foregoing, it is desirable to have a greater precision in change of capacitance measurements to permit studies to be made of the changes as a function of chemical data obtained during a deterioration. The change in dielectric constant of an oil during a reasonable deterioration may be of the order of a few per cent and it would be desirable to determine such a change to a precision of plus or minus one per cent. It is believed that these values may be obtained.

Initially the conventional (Thomas)-Schering bridge (source-symmetrical bridge since symmetry obtains with respect to source terminals) was used for these measurements. However for the foregoing conditions, this type of bridge is quite unsatisfactory from the point of view of inherent sensitivity at low frequencies due to the large difference in impedance of the measuring cell and the measuring arms. Consequently the conventional conjugate (Thomas)-Schering bridge (detector-symmetrical bridge since symmetry obtains with respect to detector terminals) was used because it has a greater inherent bridge sensitivity under the foregoing conditions. However, it was found that with measuring cells of low

capacitance that this type of bridge is practically impossible to operate, due to the fact that the bridge and guard or shield (Wagner[1] ground) balances are so closely dependent.

Further study of a generalized bridge network showed that the precision and dependency of balances of a general five-terminal bridge network is a function of three dependent balances and a dependency factor which is a function of the ratios of certain impedances in the bridge network. This paper evaluates these factors and shows that for certain values of bridge constants and frequency, the use of three balances is a practical necessity and in general permits simplified bridge construction and operation.

II. General Bridge Network

In general, accurate dielectric measurements of small insulating-oil samples with low power factors require a three-terminal measuring cell and reference capacitor. Thus a five-terminal bridge network is required. Since a general five-terminal impedance network will consist of a minimum of ten impedances, of which two will be impedances across diagonally opposite terminals, the impedances of the source and of the detector, a minimum of eight impedances must be considered in the balance relations. All of the impedances must be considered in connection with the bridge sensitivity. Such a generalized bridge network is shown in figure 1*a*.

Since there are eight impedances to be considered in the balance relations it is advisable to consider the nature of these impedances. Four of these impedances will be in the bridge arms *AM*, *AN*, *BM*, and *BN* in figure 1*a* and the remaining four will be from the bridge terminals to shield or guard (ground in figure 1*a*) *AG*, *BG*, *MG*, and *NG*. The bridge arms consist of two measuring arms made up of resistors and capacitors in parallel arrangement and two arms containing a reference capacitor (or capacitors when a substitution method is used) and a measuring cell. Now since each of these bridge arms is shielded, each arm individually forms a three-terminal network, thereby introducing three individual impedances. For example, consider a three-terminal reference capacitor in bridge arm *AN* of figure 1*a*, the impedance from the source electrode to the bridge electrode will be the impedance Z_2, the impedance from the bridge electrode to guard electrode and the impedance from the bridge lead to its shield as introduced by mechanical supports or by other means will be in part the impedance Z_5 (the remaining part arises similarly from arm *BN*), the impedance from source electrode to guard and from the source lead to its shield as introduced by mechanical supports or by other means will be in part the impedance Z_3 (the remaining part arises similarly from *AM*).

The extraneous bridge arms *AG*, *BG*, *MG*, and *NG* of figure 1*a*, may contain in addition to the inherent impedances as outlined in the foregoing and arising from the bridge construction, definite controllable impedances (such as resistors, capacitors, and inductors) for varying the impedances of these arms as may be required for desired bridge operation and precision. The generalized bridge network will contain such controllable impedances in each of these arms.

III. General Balance Relations

For the generalized bridge network figure 1*a* Balsbaugh and Moon[2] have shown that the detector points *M* and *N* will have equal potentials for the condition of

$$\begin{aligned}&Z_1Z_2Z_5Z_6Z_7+Z_2Z_3Z_4Z_7Z_8+Z_2Z_4Z_5Z_6Z_7+\\&\quad Z_2Z_3Z_5Z_6Z_7+Z_2Z_3Z_4Z_6Z_7+Z_2Z_3Z_4Z_5Z_7-\\&\quad Z_1Z_2Z_4Z_6Z_8-Z_1Z_3Z_4Z_5Z_8-Z_1Z_4Z_5Z_6Z_8-\\&Z_1Z_3Z_5Z_6Z_8-Z_1Z_3Z_4Z_6Z_8-Z_1Z_3Z_5Z_7Z_8=0\end{aligned} \tag{1}$$

The balances necessary to satisfv (3) may be obtained by rewriting (1) as follows:

$$\begin{aligned}&(Z_2Z_7-Z_1Z_8)(Z_4Z_5Z_6+Z_3Z_5Z_6+Z_3Z_4Z_6+\\&\quad Z_3Z_4Z_5+Z_2Z_4Z_6)+Z_7(Z_1Z_5-Z_2Z_4)(Z_2Z_6-\\&\qquad Z_3Z_8)=0\end{aligned} \tag{2}$$

Thus (2) shows that to permit the use of the bridge balance relation

$$Z_2Z_7=Z_1Z_8 \tag{3}$$

there must simultaneously be satisfied in addition to (3) either of the relations

$$Z_1Z_5=Z_2Z_4 \tag{4}$$

or

$$Z_2Z_6=Z_3Z_8 \tag{5}$$

With (3) satisfied (4) and (5) may also be expressed as (6) and (7) respectively

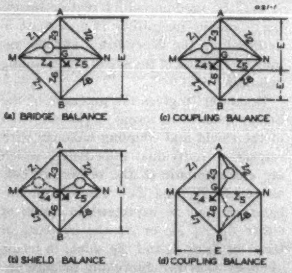
$$Z_5Z_7=Z_4Z_8 \tag{6}$$

$$Z_1Z_6=Z_3Z_7 \tag{7}$$

Thus in general there are three dependent balances in establishing relations between the arms of the general bridge network. The relation $Z_2Z_7=Z_1Z_8$ is termed a bridge balance, the relation, $Z_2Z_6=Z_3Z_8$ or $Z_1Z_6=Z_3Z_7$, is termed a shield balance, and the relation, $Z_1Z_5=Z_2Z_4$ or $Z_5Z_7=Z_4Z_8$, is termed a coupling balance. Note that there are two unique impedances with respect to each of the coupling and shield balances namely, Z_4, Z_5 and Z_3, Z_6 respectively. Accordingly the impedances Z_4 and Z_5, the impedances from the detector terminals to shield, are termed the coupling impedances in view of the fact that they give a coupling from the bridge balance points to shield, and the impedances Z_3 and Z_6, the impedances from the source terminals to shield, are termed the shield impedances.

It is important to note that the coupling and shield balances are fundamentally different. In the shield or guard balance the shields and guards are balanced to the same potential as the bridge detector terminals (bridge sections of the measuring cell and reference capacitor) whereas in the coupling balance the shields and guards must be at a different potential than the bridge detector terminals. It is furthermore important to note that in (*a*) a five-terminal bridge network using a three terminal measuring cell and reference capacitor the guard and shield balances are made simultaneously and that in (*b*) a five-terminal bridge network consisting of a shielded our-arm bridge using two terminal measuring and reference capacitors, the guards are absent and only a shield balance may be made. The use of three balances and the theory developed applies to both (*a*) and (*b*) and since the shield balance is common to both, the term shield balance is used. Thus in the present case shield and guard balances are synonomous.

The methods used in obtaining the three balances are shown in figures 1*a*, 1*b*, 1*c*, and 1*d*. Figure 1*a* shows the detector in position for bridge balancing $Z_1Z_8=Z_2Z_7$. Figure 1*b* shows the detector in either of two positions for shield balancing, $Z_2Z_6=Z_3Z_8$ or $Z_1Z_6=Z_3Z_7$, the preferred position depending upon the



(a) BRIDGE BALANCE (c) COUPLING BALANCE

(b) SHIELD BALANCE (d) COUPLING BALANCE

Figure 1. Balancing arrangements

---

relative magnitudes of the impedances in the arms involved in either balance and thus affecting the resulting sensitivity. Figure 1*c* shows the detector in position for coupling circuit balancing $Z_1Z_5=Z_2Z_4$ or $Z_6Z_7=Z_4Z_8$, the detector being in the normal bridge balancing position and with the source voltage being applied either between *A-G*, *B-G*, or between *G* and *A* connected to *B*. Figure 1*d* also shows an optional arrangement for coupling circuit balancing with the detector circuit in either of two positions. Note that in the latter case the source and detector terminals are interchanged so that the shield and coupling arms are interchanged with balance obtained similarly to the normal shield balance. The preferred arrangements for coupling circuit balances depend upon the facility and practicability of the switching operations and the resulting sensitivity obtainable.

Since it has been shown that there are three balances determining the bridge operation and measurement it is desirable to define and determine the dependency of the balances. The interrelation between any two balances or the dependency may be definitely defined by considering figure 1*a* in which the detector is in position for bridge balancing. This dependency may be obtained either for the general case assuming any degree of unbalance in each of the three balances or for the specific case in which all three balances are close to balance. Taking the latter case since it is of greatest importance, assume that the circuit impedances in figure 1*a* are such that three balances are satisfied to some desirable precision and that the shield balance is unbalanced by changing Z_6, this change being either in the real component (capacitance-factor unbalance) or imaginary component (power-factor unbalance). These changes may be made individually or simultaneously. Now, in general, a deflection will appear in the detector indicating the bridge circuit is out of balance, the magnitude of this will depend upon the degree of unbalance in the shield balance, the degree of unbalance of the coupling balance and the bridge constants and frequency. The apparent unbalance in the bridge may now be corrected by changing any one of the bridge impedances, say Z_7, either real or imaginary components or both as required, to give again a bridge balance. The ratio of the per-unit change from balance in Z_7 (the change in Z_7 expressed as a ratio of Z_7) to the per-unit change in Z_6 (the change in Z_6 expressed as a ratio of Z_6) gives a quantitative measure of the dependency between the bridge and shield balances. This quantity may be complex, indicating a power-factor unbalance in one circuit gives a capacitance factor unbalance in the other circuit or vice versa. This same procedure may be used to obtain quantitatively the dependency between any two of the three dependent balances.

Since in general for precise measurements the dielectric constant and power factor of the sample must be obtained from (3) it is advisable to investigate the precision of the coupling balance as given by (4) or (6) and the shield balance as given by (5) or (7) on the validity of (3). Also since there are three dependent balances it is advisable to investigate the conditions determining the degree of dependency of these balances on each other. From the point of view of the mechanics of the balancing it is desirable to have these three balances relatively independent. The foregoing are analyzed in IV.

Kouwenhoven and Banos[3] have shown that "in a completely guarded and shielded bridge it is advisable to keep the cross capacitances existing between the measuring circuits and the guard circuits low" and that "in such a bridge it is of prime importance that the conductances of the cross capacitances be maintained at zero". Balsbaugh and Moon[2] showed the significance of the difference of the coupling impedances in the bridge balance and Balsbaugh and Herzenberg[4,5] showed that there were three balances in a five-terminal network and gave a procedure for obtaining a capacitance factor balance for the coupling circuit.

IV. Bridge Balance as Affected by Shield and Coupling Balances

1. GENERAL RELATIONS

To determine quantitatively the dependency of the balances and the precision of the shield and coupling balances as affecting the precision or validity of the bridge balance assume that (3), (4), and (5), the three balance relations, are not satisfied and that

$$Z_2Z_7-Z_1Z_8-Z_8\Delta Z_1=0 \tag{8}$$

$$Z_1Z_5-Z_2Z_4-Z_2\Delta Z_4=0 \tag{9}$$

$$Z_3Z_8-Z_9Z_6-Z_9\Delta Z_6=0 \tag{10}$$

in which ΔZ_1, ΔZ_4, and ΔZ_6 are the changes in impedances Z_1, Z_4, and Z_6 respectively to effect the bridge, coupling and shield balances respectively. Substituting (8), (9), and (10) in (2) gives

$$\frac{\Delta Z_1}{Z_1}=\frac{\Delta Z_4}{Z_4}\,\frac{\Delta Z_6}{Z_6}D \tag{11}$$

in which D is the dependency factor and

$$\frac{1}{D}=\left(\frac{Z_1Z_8}{Z_2Z_7}\right)\left(\frac{Z_5}{Z_2}+\frac{Z_6Z_3}{Z_9Z_4}+\frac{Z_8}{Z_2}+\frac{Z_8Z_6}{Z_9Z_4}+1\right) \tag{12}$$

and $\Delta Z_1/Z_1$, $\Delta Z_4/Z_4$, and $\Delta Z_6/Z_6$ are the per-unit complex changes required in Z_1, Z_4, and Z_6 to effect the three balances. These complex per-unit changes may be expressed in terms of a real per-unit change, q (capacitance-factor unbalance) and an imaginary per-unit change, p (power-factor unbalance). Thus

$$\frac{\Delta Z_1}{Z_1}=q_1+jp_1 \tag{13}$$

$$\frac{\Delta Z_4}{Z_4}=q_4+jp_4 \tag{14}$$

$$\frac{\Delta Z_6}{Z_6}=q_6+jp_6 \tag{15}$$

Thus, this procedure permits the effects of shield and coupling circuit unbalances to be directly evaluated in terms of precision of power-factor and capacitance-factor measurements in the bridge circuit or sample. A discussion of these per unit capacitance factor and power factor quantities and their determination in terms of the resistance and capacitances in any arm is given in IV-2. Substituting (13), (14), and (15) in (11) gives

$$(q_1+jp_1)=(q_4+jp_4)(q_6+jp_6)D \tag{16}$$

Note that (16) is a perfectly general relation and is independent of the closeness of balance of either of the three balances, of the nature of the inherent impedances in the bridge network, and of the impedances in the bridge arms.

The dependency factor D for the condition of all three balances close to balance may be simplified from (12) by using (3), (4), and (5). This gives

$$\frac{1}{D}=\frac{Z_5}{Z_2}+\frac{Z_3}{Z_1}+\frac{Z_8}{Z_2}+\frac{Z_9}{Z_6}+1 \tag{17}$$

The dependency factor D is a function of ratios of impedances appearing in the different balances, coupling and shield to bridge. It is in general complex although it may be predominantly real or imaginary, and its magnitude is important in determining the dependency and the required precision of the shield and coupling balances.

Equation 16 gives the precision of the bridge balance in terms of the precision of the shield and coupling balances with respect to individual impedances which are characteristic of the respective balances, Z_1, Z_4, and Z_6. The bridge unbalances may be expressed in terms of either Z_1, Z_2, Z_7, or Z_8, the coupling in terms of Z_4 or Z_5 and the shield in terms of either Z_3 or Z_6. Since any balance determines the relation between four impedances it is possible to express a per-unit change of one of the impedances in terms of the equivalent change from balance in one of the other impedances. Consider figure 1*a* and diagonally opposite impedances Z_1 and Z_8 changed from balance by ΔZ_1 and ΔZ_8 respectively. Then

$$Z_2Z_7-(Z_1+\Delta Z_1)(Z_8+\Delta Z_8)=0 \qquad (18)$$

and neglecting second order terms

$$\frac{\Delta Z_1}{Z_1}=-\frac{\Delta Z_8}{Z_8} \qquad (19)$$

or

$$(q_1+jp_1)=-(q_8+jp_8) \qquad (20)$$

Similarly for any two adjacent impedances in the bridge for example Z_7 and Z_8 and a change from balance of ΔZ_7 and ΔZ_8 respectively, gives

$$Z_2(Z_7+\Delta Z_7)=Z_1(Z_8+\Delta Z_8) \qquad (21)$$

$$\frac{\Delta Z_7}{Z_7}=\frac{\Delta Z_8}{Z_8} \qquad (22)$$

$$q_7+jp_7=q_8+jp_8 \qquad (23)$$

Thus using relations similar to (20) and (23), (16) may be expressed for the bridge, coupling, and shield unbalances in terms of any impedance which is unique with respect to that balance.

2. Per-Unit Changes in Impedances

A per-unit change in an impedance is defined as the change in the impedance from an initial value to a final value expressed as a ratio of the initial value. Since in general the impedance will consist of a real and an imaginary component, the per-unit change in impedance will consist of a real and an imaginary component, the real part of the per-unit change being expressed as a per-unit capacitance-factor change q, and the imaginary part of the per-unit change being expressed as a power-factor change p. The arms of the bridge network may be considered conveniently to be essentially resistive (measuring arm with resistance in parallel with capacitance) or capacitive (reference capacitor or measuring cell represented by resistance in series with a capacitance). Thus for a capacitance C_p in parallel with a resistance R_p

$$Z_p=\frac{R_p-j\omega R_p^2C_p}{1+\omega^2R_p^2C_p^2} \qquad (24)$$

$$Z_p+\Delta Z_p=\frac{(R_p+\Delta R_p)-j\omega(R_p+\Delta R_p)^2(C_p+\Delta C_p)}{1+\omega^2(R_p+\Delta R_p)^2(C_p+\Delta C_p)^2} \qquad (25)$$

and from (24) and (25) $\Delta Z_p/Z_p$ may be determined and

$$\frac{\Delta Z_p}{Z_p}=(q_p+jp_p) \qquad (26)$$

For the common condition of $\omega R_pC_p<0.1$, and for relatively small values of q_p and p_p (26) becomes

$$\frac{\Delta Z_p}{Z_p}=q_p+jp_p\cong\frac{\Delta R_p}{R_p}-j\omega R_p\Delta C_p \qquad (27)$$

For example with a resistance, $R_p=10^5$ ohms, in parallel with a capacitance, $C_p=100$ micromicrofarads and $f=60$ cycles, a change in R_p to 100, 100 ohms and in C_p to 126.5 micromicrofarads gives $\Delta R_p=100$ ohms and $\Delta C_p=26.5$ micromicrofarads. Then from (27) $\Delta Z_p+Z_p=0.001-j0.001$. This gives a positive per-unit capacitance-factor change and a negative per-unit power-factor change in Z_p of 0.001.

For a capacitance C_s in series with a resistance R_s

$$Z_s=R_s-j\frac{1}{\omega C_s} \qquad (28)$$

$$Z_s+\Delta Z_s=R_s+\Delta R_s-j\frac{1}{\omega(C_s+\Delta C_s)} \qquad (29)$$

and from (28) and (29) $\Delta Z_s/Z_s$ may be determined and

$$\frac{\Delta Z_s}{Z_s}=q_s+jp_s \qquad (30)$$

For the common condition of $\omega R_sC_s<0.1$, and for relatively small values of q_s and p_s (30) becomes

$$\frac{\Delta Z_s}{Z_s}=q_s+jp_s\cong-\frac{\Delta C_s}{C_s}+j\omega\Delta R_sC_s \qquad (31)$$

For example, with a resistance $R_s=10^6$ ohms in series with a capacitance $C_s=10$ micromicrofarads and $f=60$ cycles, a change in R_s to 1,265,000 ohms and in C_s to 10.01 micromicrofarads gives $\Delta R_s=265{,}000$ ohms and $\Delta C_s=0.01$ micromicrofarad. Then from (31) $\Delta Z_s/Z_s=-0.001+j0.001$. This gives a negative per-unit capacitance-factor change and a positive per-unit power-factor change of 0.001.

3. Application to Detector-Symmetrical Bridge

Consider the detector-symmetrical bridge in figure 2*a* with impedance designation corresponding to figure 1*a* for similar positions in the network. It is now desired to determine the effect of the precision of shield and coupling balances on the precision of the bridge balance for (*a*) condition of all balances close to balance and (*b*) for condition of coupling circuit far out of balance as would be the case when no provision is made for a coupling balance (arms *qr*, *sg*, and *vu*, *tg* open figure 2*a*) and with the shield and bridge balances close to balance.

(*a*). For the condition of all three balances close to balance the effect of coupling and shield unbalances on the bridge balance is given in general by (16) with the dependency factor D given by (12) or (17). The per-unit changes in impedances Z_1, Z_4, and Z_6 may also be expressed in terms of their resistance and capacitance components,

$$\frac{\Delta Z_1}{Z_1},\ \frac{\Delta Z_6}{Z_6},\ \text{and}\ \frac{\Delta Z_4}{Z_4}\ \text{by (27)}$$

(for this type of bridge Z_4 must be essentially resistive and Z_6 essentially capacitive). Substituting these into (16)

$$\left(\frac{\Delta R_1}{R_1}-j\omega R_1\Delta C_1\right)=\left(\frac{\Delta R_4}{R_4}-j\omega R_4\Delta C_4\right)\times\left(\frac{\Delta R_6}{R_6}-j\omega R_6\Delta C_6\right)D \qquad (32)$$

Values of the dependency factor D for certain typical bridge-arm constants and for different frequencies are given by (*a*) to (*f*) in table I. It may be noted that the values are relatively large and vary from $0.49+j0.00$ at 60 cycles to $0.18-j0.06$ at 10,000 cycles and the assumed constants. Thus taking the constants as given by (*a*) table I in which $D=0.49+j0.00$, (32) and (16) indicate that to give $q_1=p_1=\pm10^{-6}$ requires, for the shield and coupling circuits balanced to the same precision in capacitance factor and power factor, that $q_4=q_6=p_4=p_6=\pm10^{-3}$. This shows that for this particular case of bridge operation (with the resistances in the shield and coupling arms set to within one part in a thousand and with the capacitances set to within an ωRC of 0.001 in these same arms) the measured bridge power factor as affected by the extraneous

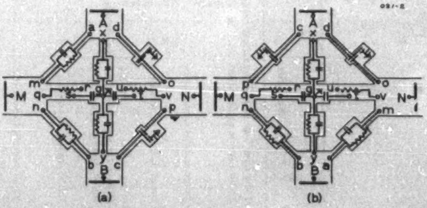

Figure 2. Generalized bridge network

(*a*)—Conjugate Schering or detector - symmetrical connection

(*b*)—Schering or source - symmetrical connection inherent bridge impedances or by the shield and coupling balances will be within $\pm 10^{-6}$. Similarly if it is desired to have $q_1 = p_1 = \pm 10^{-4}$, it is necessary to have $q_4 = q_5 = p_4 = p_5 = \pm 10^{-2}$. The foregoing indicates quite satisfactory bridge operation in that close balancing of the shield and coupling circuits is not required.

(*b*). However, now consider the case in which a coupling balance is not used and the coupling impedances Z_4 and Z_5 are determined entirely by the bridge construction. This case is represented by (*g*) in table I in which the coupling impedances Z_4 and Z_5 correspond to 400 micromicrofarads at 60 cycles, $D = 0.95 - j0.00$ and $q_4 + jp_4 = -1.00 + j0.00$. Thus (16) becomes

$$(q_1 + jp_1) = -0.95(q_4 + jp_4) \qquad (33)$$

This indicates that the bridge and shield balances are almost directly coupled (unit coupling) and that the shield must be balanced as precisely as the bridge. For low power factors and high-precision measurements this is a practical impossibility in view of the nature of the inherent impedances comprising the shield balance. Of equal importance is the fact that balance of the shield and coupling circuits could not be made since the two balances cannot be separated in the balancing operation.

4. APPLICATION TO SOURCE-SYMMETRICAL BRIDGE

Consider the source-symmetrical bridge in figure 2*b* with impedance designation corresponding to figure 1*a* for similar positions in the network. It is now desired to determine the effect of the precision of the shield and coupling balances on the precision of the bridge balances for (*a*) condition of all balances close to balance and (*b*) for the condition of shield and bridge circuits close to balance and the coupling circuit far out of balance, as would obtain when no provision is made for this balance and (1) the inherent impedances Z_4 and Z_5 are such that these values are far out of balance due to bridge construction or (2) even if these impedances are normally reasonably close to balance they are thrown far out of balance as a result of high humidity changing their loss component.

(*a*). For the condition of all three balances close to balance, the effect of coupling and shield unbalances on the bridge balance is given in general by (16) with the dependency factor D given by (12) or (17). The per-unit changes in impedances Z_1, Z_4, and Z_5 may also be

In all cases the bridge and shield balances are made, the coupling balance is or is not made as indicated. The power factor of the sample, the reference condenser, and one of the inherent impedances is taken as zero. This makes the impedances for balance independent of frequency and it has only a slight effect on *D*.

expressed in terms of their resistance and capacitance components, $\Delta Z_1/Z_1$ by (31), $\Delta Z_6/Z_6$ by (27), and $\Delta Z_4/Z_4$ by either (27) or (31), depending upon whether Z_4 and Z_6 are both essentially resistive or capacitive respectively (arms *qr*, *sg* and *vu* and *tg* in series or parallel, respectively, figure 2*b*). Equation 16 now gives

$$\left(-\frac{\Delta C_1}{C_1}+j\omega\Delta R_1C_1\right)=\left[\left(-\frac{\Delta C_4}{C_4}+j\omega\Delta R_4C_4\right)\right.$$
$$\left.\text{or}\left(\frac{\Delta R_4}{R_4}-j\omega R_4\Delta C_4\right)\right]\left(\frac{\Delta R_6}{R_6}-j\omega R_6\Delta C_6\right)D \tag{34}$$

Values of the dependency factor *D* for this type of bridge and for certain bridge constants and for different frequencies are given by *j* to *o*, table I, for the coupling impedances being essentially capacitive and by *s* to *u*, table I, for the coupling impedances being essentially resistive. These values of *D*, for the cases given, vary from $0.0000+j0.0015$ to $0.125+j0.117$. Thus they show quite a range in magnitude and also in the angle of *D*.

(*b*). Now consider the condition of the shield and bridge circuits balanced and the coupling circuit out of balance due to no provision for this balance and resulting from bridge construction or operating conditions. This condition is represented by *p* to *r*, table I, and gives values of *D* from $0.0000+j0.0015$ to $0.125+j0.142$ with $q_4+jp_4=-0.75+j0.00$ for the assumed bridge constants. The inherent coupling impedances in the source-symmetrical bridge are normally capacitive although they may have substantial loss components. Thus even though the capacitance components are approximately equal in the bridge construction the loss components may be unequal giving a significant value of p_4. Furthermore, when no provision is made for coupling balance q_4 or p_4 may have relatively large values resulting from (*a*) high humidity, (*b*) use of different measuring cells or reference capacitors with different inherent coupling impedances, and (*c*) use of the bridge with other than equal-ratio arms.

5. Precision of Bridge Balance in Terms of Precision of Shield and Coupling Balances and Dependency Factor

The precision of the bridge balance in terms of the precision of the shield and coupling balances and the dependency factor may be readily obtained from (16). There are two conditions of particular interest: (*a*) all three balances made and with the shield and coupling balances of equal precision in both capacitance factor and power factor, and (*b*) only two balances made, bridge and shield, with various values of q_4 and p_4.

(*a*). For this condition (16) may be expressed giving the assumed equal precision of coupling and shield balances, q_4, p_4, and q_6, p_6 respectively in terms of the desired precision of the bridge measurements q_1 and p_1 and the real and imaginary components D_r and D_i respectively of the dependency factor. This gives

$$\pm q_4=\pm q_6=\pm p_4=\pm p_6=\sqrt{\frac{\pm q_1=\pm p_1}{2(D_r+D_i)}} \tag{35}$$

Equation 35 gives the greatest precision required of any of q_4, q_6, p_4, and p_6. In (35) D_r and D_i are always positive and independent of the algebraic sign as determined from *D*.

Representative values from (35) are given in table II.

Table II

D_r	D_i	$\pm q_4=\pm q_6=\pm p_4=\pm p_6$ for $\pm q_1=\pm p_1=\pm 10^{-6}$	 for $\pm q_1=\pm p_1=\pm 10^{-4}$
1	0	$0.71(10^{-3})$	$0.71(10^{-2})$
0	1	$0.71(10^{-3})$	$0.71(10^{-2})$
1	1	$0.5\ (10^{-3})$	$(0.5)10^{-2}$
0.01	0	$0.71(10^{-2})$	$0.71(10^{-1})$
0	0.01	$0.71(10^{-2})$	$0.71(10^{-1})$
0.01	0.01	$(0.5)10^{-2}$	$0.5(10^{-1})$
0.1	0.01	$2.13(10^{-3})$	$2.13(10^{-2})$
0.01	0.1	$2.13(10^{-3})$	$2.13(10^{-2})$

q_4, q_6 (capacitance factors) and p_4, p_6 (power factors) are precisions of shield and coupling balances—q_1, p_1 are precisions of bridge balance—D_r, D_i are real and imaginary components of dependency factor *D*.

Thus (35) and table II show that for the limiting practical case the required precision of the shield and coupling balances ($\pm q_4=\pm q_6=\pm p_4=\pm p_6$) is equal to 0.71 times the square root of the desired precision of the bridge balance ($\pm q_1=\pm p_1$). As the value of the dependency factor gets smaller the required precision of the shield and coupling balances under the foregoing conditions gets less for a given precision of bridge balance. Even for high-precision bridge balance the required guard and coupling balance precisions are very readily obtainable.

(*b*). For this condition (16) may be expressed giving the required shield precision $\pm q_6$ and $\pm p_6$ in terms of desired bridge precision $\pm q_1$ and $\pm p_1$ for specific values of q_4, p_4, D_r, and D_i (since in this case no coupling balance is made and q_4 and p_4 depend on the bridge construction or operating conditions). This gives

$$\pm q_6=\pm\frac{q_1(q_4D_r-p_4D_i)-p_1(p_4D_r+q_4D_i)}{(q_4D_r-p_4D_i)^2+(p_4D_r+q_4D_i)^2} \tag{36a}$$

$$\pm p_6=\pm\frac{p_1(q_4D_r-p_4D_i)-q_1(p_4D_r+q_4D_i)}{(q_4D_r-p_4D_i)^2+(p_4D_r+q_4D_i)^2} \tag{36b}$$

In (36*a*) and (36*b*), q_4, p_4, D_r, and D_i must have their proper algebraic sign.

Representative values from (36*a*) and (36*b*) are given in table III.

Thus (36*a*), (36*b*), and table III show that for the limiting practical condition the required shield balance precision ($\pm q_6$ and $\pm p_6$) may approximate either of the desired bridge balance precision ($\pm q_1$ and $\pm p_1$) depending upon the relative magnitudes of the D_r, D_i, q_4, and p_4.

V. Advantages to Be Gained From the Use of Three Balances and a Generalized Bridge Network

It is not to be inferred from the foregoing that precise measurements cannot be obtained with bridges not utilizing more than two balances. However it is maintained that the use of three balances and a generalized bridge network

(*a*). Permits more rapid balancing since the dependency of the balances is maintained at a minimum as the circuits are progressively balanced to a higher precision in the balancing operation.

(*b*). Permits simplified shield circuits in that less precise balances are required when the coupling circuit is balanced.

(*c*). Permits greater flexibility in design of bridges, reference capacitors, and measuring cells in that complete control of all inherent impedances is obtained.

(*d*). Is definitely required for certain types of bridges, namely, the detector-symmetrical

Table III

± 0.01	0	0	± 0.5	$\pm 0.2(10^3)p_1$	$\pm 0.2(10^3)q_1$
0	± 0.01	± 0.5	0	$\pm 0.2(10^3)p_1$	$\pm 0.2(10^2)q_1$

See notes at bottom of table II.

bridge utilizing measuring cells having low capacitances.

(*e*). Prevents difficulties with bridge measurements due to a change in nature of the inherent impedances. For example with the source-symmetrical bridge, high humidity may sufficiently change the real components of the coupling impedances so that there is difficulty in balancing and that sufficiently precise measurements cannot be obtained.

VI. Relative Bridge Sensitivity

It is of interest to determine the relative bridge sensitivity with the bridge operated with detector symmetry as compared to source symmetry. For the bridge considered by itself (for the present neglecting shield and coupling circuits) the voltage across the detector E_{9s} with applied bridge voltage E for the condition of source symmetry is (impedance designations, figure 1*a*, bridge circuits figure 2*b*)

$$E_{9s}=\frac{(Z_2Z_7-Z_1Z_8)Z_9E}{Z_1Z_2(Z_7+Z_8+Z_9)+Z_7Z_8(Z_1+Z_2+Z_9)+Z_9(Z_2Z_7+Z_1Z_8)} \tag{37}$$

and E_{9s} is zero for $Z_2Z_7=Z_1Z_8$. The magnitude of this voltage for a given per unit capacitance or power-factor unbalance of the bridge may be determined by considering the bridge unbalanced by ΔZ_1 in Z_1. Then

$$Z_2Z_7-Z_1Z_8-\Delta Z_1Z_8=0 \tag{38}$$

$$\Delta Z_1Z_8=Z_2Z_7-Z_1Z_8 \tag{39}$$

the latter may be written

$$Z_2Z_7-Z_1Z_8=\frac{\Delta Z_1}{Z_1}Z_1Z_8=(q_1+jp_1)(Z_1Z_8) \tag{40}$$

Substituting (40) in (37) will give E_{9s} for given values of per unit or absolute power factor change p_1 and per unit capacitance factor change q_1 of impedance Z_1.

Now under similar conditions with the bridge having detector symmetry the value of E_{9d} may be obtained from (37) by interchanging impedances Z_1 and Z_8 (then impedance designation is that of figure 1*a* with impedances Z_1 and Z_8 interchanged, bridge circuit is that of figure 2*a*). This gives

$$E_{9d}=\frac{(Z_2Z_7-Z_1Z_8)Z_9E}{Z_1Z_2(Z_7+Z_8)+Z_7Z_8(Z_1+Z_2)+Z_9(Z_2Z_7+Z_1Z_8)+Z_9(Z_1Z_7+Z_2Z_8)} \tag{41}$$

and E_{9d} may be expressed in terms of per-unit p_1 or q_1 unbalances in Z_1, by substituting (40) in (41).

For equal per-unit unbalances in Z_1, the relative bridge sensitivity of the bridge with detector symmetry as compared to the case with source symmetry may be obtained by taking the ratio of (41) to (37) with equal numerators for each equation. This gives

$$\frac{E_{9d}}{E_{9s}}=\frac{Z_1Z_2(Z_7+Z_8+Z_9)+Z_7Z_8(Z_1+Z_2+Z_9)+Z_9(Z_2Z_7+Z_1Z_8)}{Z_1Z_2(Z_7+Z_8)+Z_7Z_8(Z_1+Z_2)+Z_9(Z_2Z_7+Z_1Z_8)+Z_9(Z_1Z_7+Z_2Z_8)} \tag{42}$$

Two cases are of particular interest; (*a*) the impedance of the oil cell Z_1, the impedance of the reference capacitor Z_2, and the input impedance of the detector Z_9 are of the same order of magnitude and large as compared to the measuring arms Z_7 and Z_8, and (*b*) same as for (*a*) except Z_9 is the order of magnitude of Z_7 and Z_8.

For (*a*),

$$\frac{E_{9d}}{E_{9s}}\cong\frac{Z_9}{Z_7+Z_8} \tag{43}$$

For (*b*),

$$\frac{E_{9d}}{E_{9s}}\cong\frac{Z_7+Z_8+Z_9}{Z_7+Z_8} \tag{44}$$

Thus for these conditions the detector-symmetrical bridge will give greater bridge sensitivity than the source-symmetrical bridge. The effect of the shield and coupling circuits on bridge sensitivity may be approximately determined by considering the detector input impedance Z_9' to be

$$Z_9'=Z_9\frac{(Z_4+Z_5)}{Z_9+Z_4+Z_5} \tag{45}$$

This indicates that for maximum inherent bridge sensitivity it is desirable to keep the coupling impedances of the bridge as large as possible.

VII. Conclusions

1. The balancing of any general five-terminal network is a function of three dependent balances, namely bridge, shield, and coupling.

2. The per-unit complex precision of the bridge balance of a five-terminal bridge network is equal to the product of the complex precisions of the coupling and shield balances and a dependency factor.

3. The dependency factor is in general complex and may vary between wide limits depending upon the circuit arrangement, magnitudes, and angles of the circuit impedances and frequency.

4. The use of three balances in the bridge balancing is a practical necessity under certain conditions of frequency, type of bridge, and impedances in the arms of the bridge network.

5. The use of three balances permits obtaining the minimum required precision of the coupling and shield balances to give the desired precision in the bridge balance, and therefore permits the greatest simplification and minimum range for the extraneous bridge arms.

6. The use of three balances permits the minimum time required for the bridge balancing operation in that the dependency of the balances is maintained at a minimum, thus giving the smallest number of individual balancing operations to satisfy simultaneously all the variables involved.

7. Bridge networks should be designed with the minimum number of required terminals to give the minimum number of dependent balances.

8. The theory developed is applicable to any five-terminal bridge network and is independent of the nature of the arms constituting the network.

9. When three balances are used the precision of the bridge balance can be made independent of the nature of the inherent impedances in the bridge network, the only requirement being that the inherent impedances have sufficient magnitude to separate the balances.

10. The theory developed is applicable to a shielded four terminal bridge network for measuring two terminal capacitors.

11. The shield and coupling balances are fundamentally different in that in the shield balance the shield and guard and the bridge detector terminals are balanced to the same potential whereas in the coupling balance the shield and guard and the bridge detector terminals must be at different potentials.

The "Speedomax" Power-Level Recorder

WILLIAM RUSSELL CLARK
ASSOCIATE AIEE

POWER-LEVEL and attenuation measurements are increasing in importance and a larger number of these measurements are being made each day. They are of particular importance in the radio and telephone industries where it is essential to know the power-level variations in electrical circuits and acoustic devices, the gain of amplifiers, and the attenuation of filters or communication lines at various frequencies.

Since both power-level and attenuation are measured in decibels, methods for measuring them are similar. Manual methods of obtaining these measurements have been fairly well standardized but, while they have proved to be satisfactory for some laboratory experiments, they are not applicable for many production tests. Even in some laboratory cases the time allowable for making the measurements does not permit manual methods to be used and automatic recording is necessary.

An automatic recorder for recording power level or attenuation should faithfully record rapid or slow variations in power level with time. It should be independent of frequency variations within the range of interest and record only changes in power level. In general, the faster the recorder, the more faithful the recording, provided it does not overshoot. The recorder should not move in steps, but it should draw a smooth curve on rectangular co-ordinate paper in order to eliminate the need for interpolation at any point on the record.

As a result of the need for an automatic recording device of this type, the "Speedomax" power-level recorder was developed.

In the standard manual method of making precise power-level or attenuation measurements, the instrument under test is supplied with power of the desired frequency or frequencies and its output terminals are connected to the input terminals of an attenuator which is manually adjusted so that the deflection of an indicating device across the output terminals of the attenuator remains constant for variations in input power. This indicating device, which usually consists of an a-c amplifier, a rectifier, and a meter, operates at a constant power level. Its requirements, therefore, are simple, and it is comparatively easy to design. Since precision attenuators are available, this method permits measurements to be made over wide decibel ranges with very accurate results. It eliminates two difficult problems, the designing of an a-c amplifier having reproducible characteristics over a large range of input voltage and the designing of a dynamic element with a logarithmic response.

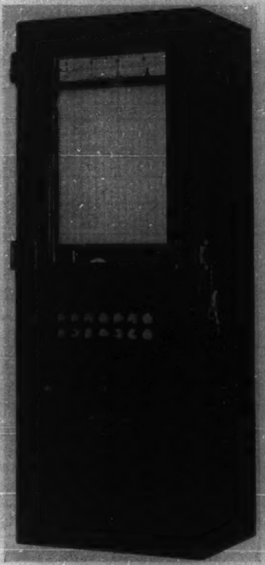

Figure 1 (above). The Speedomax power-level recorder (closed view)

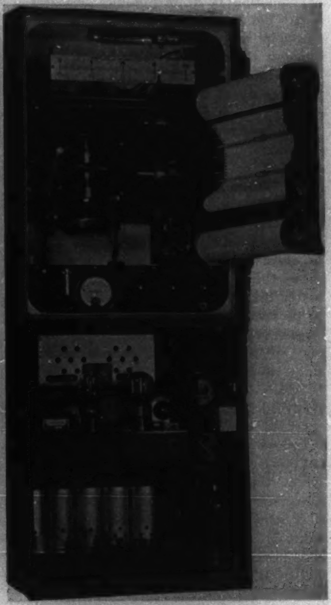

Figure 2 (right). The Speedomax power-level recorder (open view)

The basic idea of the Speedomax power-level recorder was that an automatic method should be used to make power-level and attenuation measurements that would be similar to the standard manual method. The problem was to devise an electrical circuit that would operate a recording mechanism to do this. The electrical circuit must be insensitive to frequency variations and only respond to changes in input power. The recording mechanism is similar to that of the high-speed recorder described in an article by A. J. Williams, Jr., in the 1938 AIEE TRANSACTIONS[1] and which is used to record small direct voltages.

The first instrument was completed in 1935, but the recorder described in this

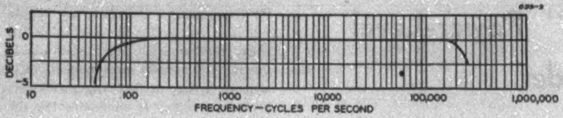

Figure 3. Frequency characteristic of the recorder

paper is a later model which has an extended frequency range (figures 1 and 2). The scale is linear in decibels (logarithmic voltage scale). It has a range of 40 decibels above a zero level of 0.01 milliwatt with an input impedance of 135 ohms. It is designed to operate between 150 and 150,000 cycles (figure 3) and over this frequency range the recorder is accurate to one-half per cent of full scale (0.2 decibel). The speed of response of the recorder is such that the pen will traverse any part of the ten-inch chart and arrive at complete balance without overshooting in approximately one second. The paper is driven by a synchronous motor at speeds of either six inches a minute or twelve inches an hour. The recorder draws a smooth curve and operates direct from a 115-volt 60-cycle supply. No batteries are used.

A sample record made by the recorder is shown in figure 4. It was obtained by applying a 1,000-cycle voltage to the input terminals of a decade attenuator which was connected to the power-level recorder. By changing the settings of the attenuator the recorder pen was made to move across the scale. This record shows the accuracy of the recorder to be better than one-half per cent, the speed to be approximately one second for the largest unbalance, the dead range to be very small, and that the recorder draws a smooth curve.

General Description

In the operation of the recorder an unknown alternating voltage is impressed across the input terminals of a continuously adjustable ladder-type slide-wire attenuator (see the block diagram, figure 5). The output of the attenuator is amplified by an a-c amplifier and rectified by the detector tube. The d-c output voltage of the detector is amplified by the d-c amplifier. The output voltage of the d-c amplifier is introduced into the converter where it is opposed by a standard direct voltage. The resultant of the two voltages is impressed across the grids of the double-triode vacuum tube of the converter. If the two voltages do not balance each other, the resultant voltage will operate one of the triode units of the converter, and the direction of unbalance will determine which unit operates. Each triode unit of the converter controls a thyratron, which in turn controls the direction of rotation of the slide-wire motor. Consequently, when one-half of the double triode operates one thyratron is turned on, the motor revolves and moves the slide-wire attenuator and the pen which are mechanically coupled to it. When the alternating voltage applied to the input terminals of the recorder changes, the motor revolves and moves the attenuator to a position that will restore the original voltage level of the a-c amplifier and balance the recorder without overshooting. Since it is desirable to avoid the use of batteries in this instrument, the constant voltages necessary for operation of the amplifiers and detectors are obtained from a regulated power supply.

In this recorder the balance point is not approached at constant speed, but the speed of rebalancing increases in proportion to the amount of unbalance. Therefore, large changes in power levels

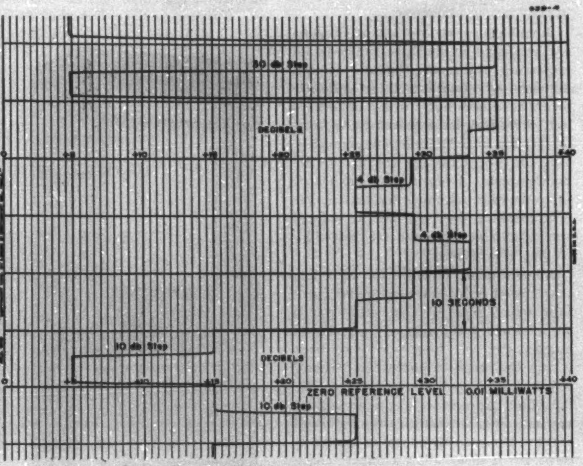

Figure 4. Chart made by recorder

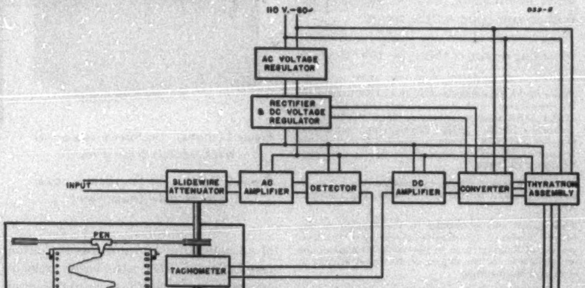

Figure 5. Block diagram of recorder

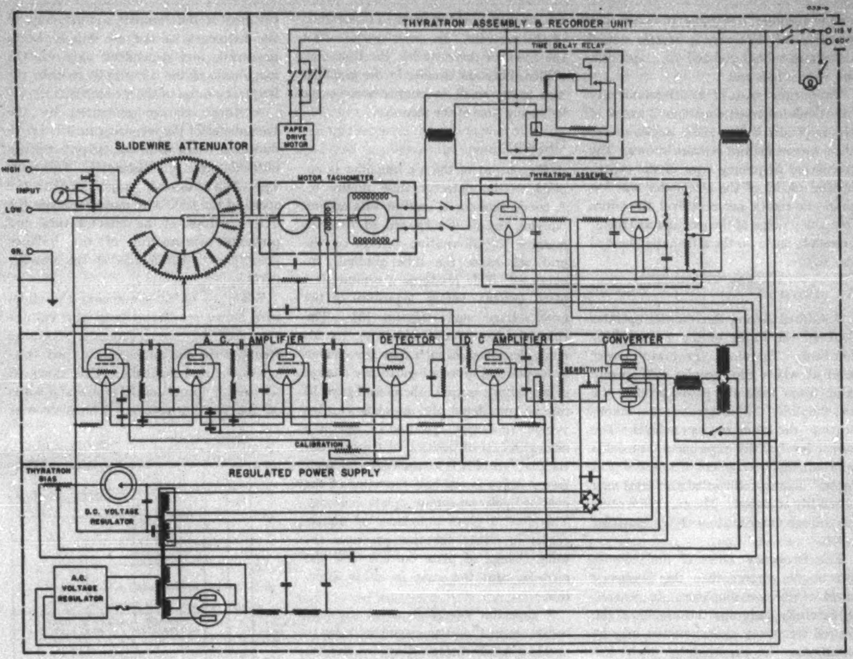

Figure 6. Schematic wiring diagram of the recorder

will be recorded approximately as fast as small changes.

Detailed Description of Component Parts

Slide-Wire Attenuator

. The decibel range and the characteristic impedance of the recorder are determined by the slide-wire attenuator. This type of attenuator is preferable to a step-by-step attenuator because its attenuation is continuously adjustable and, therefore, enables more accurate measurements to be obtained. The attenuator in this recorder has a range of 40 decibels with a characteristic impedance of 135 ohms. Slide-wire attenuators have been constructed with other decibel ranges, and with various other characteristic impedances.

The accuracy of the recorder depends on the linearity and stability of this attenuator. The linear decibel scale is obtained by using a ladder-type attenuator which is a continuously variable unbalanced π-section slide-wire attenuator (figures 6 and 7). The output of the attenuator operates into the grid circuit of a vacuum tube, which, because of its high impedance, introduces no attenuation error. Since the moving contacts of the attenuator are in this high-impedance circuit, they cause no trouble in the operation of the recorder.

The series coils are in the form of a uniform tapped slide-wire which is divided into equally spaced sections having the same resistance per section. A shunt coil is connected to each tap on the slide-wire.

In designing a slide-wire attenuator, which has a specified attenuation, the number of sections is determined by the allowable attenuation error and is independent of the characteristic impedance (see the development in the appendix). The values of the attenuation in decibels at successive shunt coils lie on a curve which is linear, but the variation in the attenuation between shunt coils is not linear (figure 8). This error, which can be made negligible by using a sufficient number of sections, can be readily calculated as is shown in the appendix. In the graphs of figure 9, which were obtained from equations 9 and 10 of the appendix, the location of the point in each attenuator section at which the attenuation error is greatest (n_{max}) and the value of this error (D_{max}) are plotted against sections per decibel (S/A). These graphs show that for values of S/A greater than $^1/_4$ the maximum error is small and occurs very close to the mid-point of each section. In this particular recorder, the range was 40 decibels and by using a 15-section slide-wire attenuator, it was made linear in decibels to one-eighth per cent (see figure 8).

These graphs apply to all unbalanced slide-wire attenuators and if the allowable error and the total attenuation is known, then the number of sections can readily be obtained. The slide-wire resistance and the shunt coils can then be calculated, to obtain any characteristic impedance.

The slide-wire attenuation must be constant over the entire frequency range of the recorder. In order to obtain this feature, the slide-wire is reverse wound on a hard-rubber rod and the shunt coils are woven resistors.

Frequency errors of the attenuator may be calculated from equations 3 and 6 of the appendix if the phase angles of the slide-wire and shunt coils are known. The calculated frequency error of the experimental model of the attenuator was less than one-eighth per cent over the entire frequency range of the recorder and measurements made on the attenuator checked this figure.

A-C AMPLIFIER

As stated before, the recorder operates to keep the input of the a-c amplifier constant. Therefore, the lowest power level at which the recorder will operate is no lower than the power level of the a-c amplifier. The greater the amplification, the lower the power level. The lowest level of the experimental model is approximately ten microwatts and a gain control is provided so that this level may be readily adjusted. The maximum overall voltage amplification of the amplifier is 300.

The frequency range of the recorder can be no greater than the frequency range of the a-c amplifier. In general, by carefully designing this amplifier, the desired frequency characteristics may be obtained. The experimental model has a three-stage resistance-capacitance coupled amplifier (figure 6) which uses screen-grid tubes. By reducing unwanted feedback to a negligible amount and using broadly tuned circuits in addition to the resistance-capacitance coupling, the frequency characteristic of the a-c amplifier is made flat to within 0.1 decibel from 150 cycles to 150 kilocycles (figure 3).

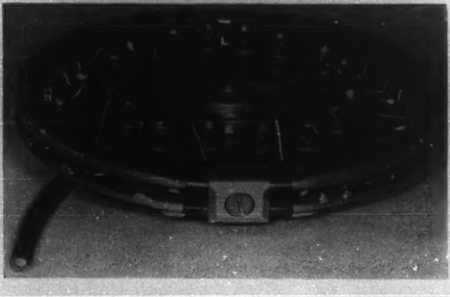

Figure 7. The slide-wire attenuator

Precautions are taken to keep any stray alternating voltages out of the a-c amplifier, as they cause an error in the reading of the recorder. In order not to affect the speed of the recorder, the time constants of certain circuits in the amplifier had to be small in comparison to the balancing time of the recorder.

DETECTOR

The output of the a-c amplifier is applied to the detector tube (figure 6). A triode detector is used and its accompanying circuit is adjusted so that increasing the alternating voltage on the grid will cause the tube gradually to overload. This produces a symmetrical plate current versus logarithm of the grid voltage curve (figure 10). The characteristic of the slide-wire, as already described, is such that any change in its position gives a logarithmic change in its voltage output, therefore figure 10 can be considered also as plate current versus slide-wire position. For the normal balanced position of the recorder the plate current is at the center of symmetry which is one-half the value of the overload or maximum plate current. Therefore, a given unbalance of the recorder in either direction produces the same change of plate current, and the recorder runs the same in either direction.

A capacitor is placed across the load resistance in the plate circuit in order to obtain a steady direct voltage by smoothing out the pulsating direct plate current flowing in the resistor. The capacity of this capacitor is limited to a value which makes the time constant of this resistance-capacitor combination low enough not to affect the speed of the recorder. The low value of this time constant affects the response of the recorder to frequencies lower than 100 cycles.

Converting the alternating voltage of the a-c amplifier to a direct voltage makes the rest of the recorder independent of the frequency of the a-c supply being measured, and dependent only on the magnitude of the a-c supply (within the frequency range of the a-c amplifier).

A direct voltage generated by the tachometer of the recording unit is introduced in series with the output voltage of the detector tube (figure 6). This voltage which is directly proportional to the speed of the slide-wire motor opposes the output voltage of the detector tube and prevents overshooting of the balance point due to the inertia of the moving parts.

When an unbalance occurs the slide-wire motor speeds up until the voltage generated by the tachometer becomes greater than the unbalance output voltage of the detector tube. This shuts off the driving torque on the motor and turns on the braking torque. The slide-wire motor slows down until the tachometer voltage becomes less than the unbalance output voltage of the detector tube, then the driving torque is again applied. This process is repeated until the recorder is brought to the balanced position which it attains without overshooting. During the balancing period the torque on the motor reverses, but the direction of rotation does not change.[1]

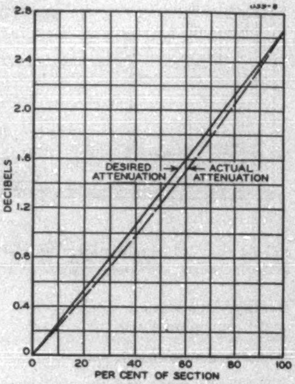

Figure 8. Accuracy graph of an attenuator section

The unbalanced voltage applied to the d-c amplifier is, therefore, alternately positive and negative during the balancing cycle, but is zero when the recorder is balanced.

For a given per cent unbalance of the

recorder, the magnitude of the d-c output voltage of the detector is greater for a large decibel range than for a small one. The magnitude of the braking voltage generated by the tachometer should approach the magnitude of the d-c output voltage of the detector. Too much tachometer voltage will make the recorder slow, while not enough voltage will allow the recorder to overshoot. If the speed of the recorder is to be independent of the decibel range, then the amount of tachometer voltage necessary to prevent overshooting will depend on the decibel range of the recorder; the larger the range, the larger the voltage required.

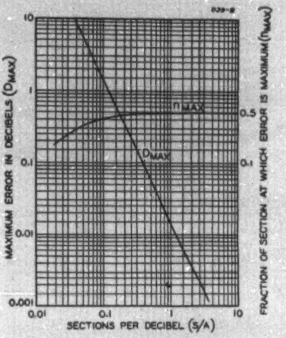

Figure 9. Maximum attenuation error and its location versus sections per decibel

The kinetic energy of the moving system is proportional to the square of the speed, but the energy which can be absorbed by the braking of the motor is proportional directly to the remaining distance to the balance point. In order to obtain maximum recorder speed without overshooting, these two energies should be equal throughout the entire decelerating period. If this is to be the case, then either the damping voltage of the tachometer should be proportional to the square of the speed or else the output voltage of the detector tube should be proportional to the square root of the unbalance.[1]

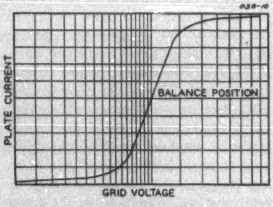

Figure 10. Plate current versus grid voltage curve of the detector

In this recorder the tachometer voltage is a linear function of the speed, but each half of the detector plate current versus logarithm of the grid voltage curve (figure 10) besides being symmetrical is approximately a square-root relationship. Thus the above requirement is satisfactorily fulfilled and the greatest speed is obtained.

D-C Amplifier

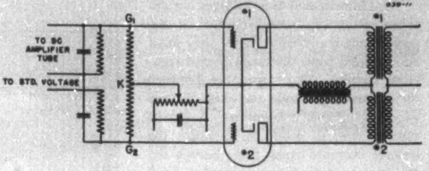
In order to obtain the desired sensitivity for the recorder, it is necessary to have a d-c amplifier since, for a small unbalance of the recorder, the voltage swing across the load resistance of the detector tube is not of sufficient magnitude to operate the converter. A single-stage screen-grid amplifier (figure 6) which has a voltage amplification of five is sufficient for recorder ranges as low as ten decibels. Lower ranges require additional amplification. A capacitor is placed across the load resistance in the plate circuit in order to smooth out any pulses which may appear in the voltage across this resistance. The time constant of this resistance-capacitor combination must also be kept low.

The Converter

The next problem is to utilize this d-c output voltage to operate the thyratrons and drive the slide-wire motor. It is not a simple one, because the d-c output of the d-c amplifier is 90 volts above ground, while the thyratrons are at ground potential. Insulating transformers must be used, but in order to use insulating transformers, the output voltage of the d-c amplifier must be transformed into an alternating voltage or used to control an alternating voltage. The alternating voltage must operate one thyratron when the output of the d-c amplifier increases, and must operate the other thyratron when the output of the d-c amplifier decreases. The converter does all of this.

The output voltage of the d-c amplifier goes to the converter (figures 6 and 11) where it is opposed by a standard direct voltage obtained from the regulated power supply. The difference between these two voltages is applied across the two resistances in the grid circuits of a double triode.

Figure 11. The converter



The grids of the double triode are biased so that when the two voltages are balanced neither section of the double triode will pass plate current.

Each plate of the double triode is connected through its own plate transformer to the same 60-cycle voltage supply. Therefore, the alternating voltage between the plate and cathode of each triode section is of the same magnitude and phase.

Referring to figure 11, if the output voltage of the d-c amplifier becomes less than the standard voltage, then G_1 will become positive with respect to K and triode number 1 will pass plate current, but since G_2 becomes negative with respect to K, triode number 2 will not pass plate current. If the output voltage of the d-c amplifier becomes greater than the standard voltage, then G_2 will become positive with respect to K, and triode number 2 will pass plate current, but since G_1 becomes negative with respect to K, triode number 1 will not pass plate current. When either triode passes plate current, a half-wave 60-cycle current flows through the primary of its plate transformer and produces a peak voltage wave across the transformer secondary. This voltage wave is, of course, the derivative of the current wave (figure 12) and is positive only one-fourth of a cycle. This is a desirable feature of the circuit, since the phasing between this voltage, which is applied to the grid of the thyratron, and the 60-cycle sine-wave plate voltage does not have to be adjusted as accurately as is generally necessary when sine-wave voltages are used on the grid as well as on the plate of the thyratron. It also insures that the thyratron will be turned on at the beginning of the positive half of its plate voltage cycle, and thus obtains maximum power output for each cycle during operation.

Since only one section of the double triode can operate at one time, only one thyratron can be turned on at one time. In this way the power, which drives the slide-wire motor, is controlled.

The filament and bias voltages are obtained from separate windings on the power-pack transformer, since they must be insulated from the main filtered regulated supply. The impedance between these windings and the high-voltage windings of this transformer should be considerable, in order to minimize the leakage currents which flow through the grid resistances of the converter tube. In order further to reduce the effect of those currents which get into the grid resistances of the tube, the impedance from G_2 to ground was made the same as the impedance from G_1 to ground (figure 11). Now the leakage currents divide equally and their resulting effect has been reduced to zero.

Up to this point in the recorder the power supply has been obtained from regulated sources. The plate voltage for the converter tube is, however, not regulated, but it is obtained from the same source as that from which the plate voltage for the thyratrons is obtained. This insures correct phasing between the voltage applied to the thyratron grids and that used on their plates. Normal line-voltage variations at this point in the recorder will cause no error in its operation.

Figure 12. Wave shapes in converter and thyratron assembly circuits

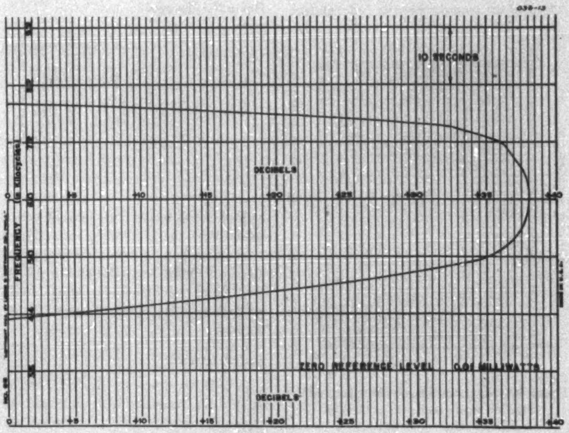

Figure 13. Frequency characteristic of a band-pass filter

Thyratron Assembly and Recording Unit

The output of the converter, as stated before, is applied to the grids of the thyratrons (figure 6) which drive the three-lead split-field series reversing motor that is mechanically coupled to the slide-wire attenuator, the tachometer, and the pen.[1] The thyratrons in this recorder perform a control function and as in all forms of control, there is a tendency to hunt. This can be eliminated by temporarily reducing the sensitivity of the control as soon as it starts operating. The sensitivity is temporarily reduced in this instrument by raising the cathode potential of the thyratrons every time they operate, and by allowing them to return to normal only gradually over a period of several cycles. The raising of the cathode potential is equivalent to depressing the grid potential and gives less sensitivity. In the common plate lead is a resistance which develops a drop of several volts upon the operation of either thyratron. This voltage drop charges a capacitor through copper-oxide rectifiers. After the thyratrons are shut off and the plate current goes to zero, the rectifiers discharge the capacitor but only gradually and in the meantime the cathodes are held more or less up from their normal zero value as is desired.

The record is made by a pen with ink on a chart ten inches wide and as long as desirable (up to 40 yards). A 12-inch length of chart is exposed. There are two paper speeds in the experimental model, 6 inches per minute or 12 inches per hour. Other paper speeds as high as $^3/_4$ inch per second have been used.

Power Supply

The power supply for the recorder, exclusive of the plate voltages for the converter and the thyratron assembly, must be very well regulated (figure 6). This is particularly true of the power supply for the detector, the d-c amplifier, and the standard voltage supply, since any variation in their power supply enters directly into the operation of the recorder and will affect its performance. Somewhat greater variations in the power supply of the a-c amplifier would be permissible since these variations do not greatly affect its gain, which is all that need be held constant. Variations in the power supply of the converter will affect only the sensitivity of the recorder.

In order to obtain a power supply which was good enough for satisfactory operation of the recorder, two separate voltage regulators were used. One regulator was of the magnetic type and operated on alternating current. It regulated the 60-cycle power supplied to the power pack-transformer. The other was a gaseous tube regulator which regulated the d-c output of the power pack. The d-c output controlled by these two regulators was constant to within 0.1 per cent for a period of 12 hours during which time the 60-cycle supply varied 10 per cent. Calculations and tests indicated that for a recorder accuracy of $^1/_2$ per cent the d-c power supply should be constant to 0.2 per cent, so the regulation obtained by this method is sufficient.

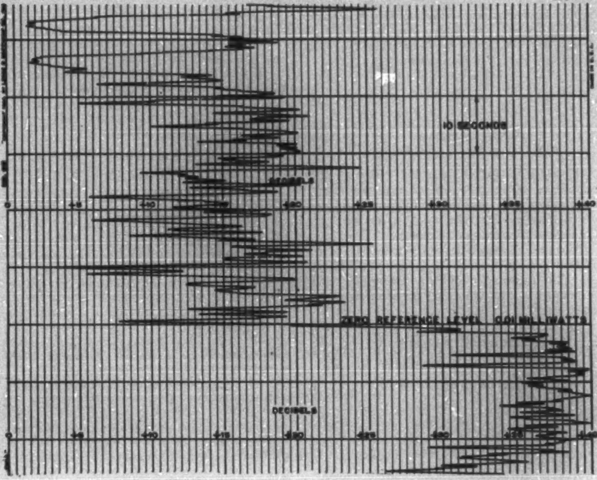

Figure 14. The fluctuating power level of a radio program

Ease of Operation

While the recorder itself is somewhat complicated, the operation of it is very simple. There are only three adjustments to be made, the "thyratron bias", the "sensitivity", and the "calibration" of the recorder (figure 6). These adjustments do not have to be made every time the recorder is used, but they should be checked occasionally.

In the calibration of the recorder, a high-resistance vacuum thermocouple voltmeter is connected across the input terminals (see figure 6). After the input voltage to the recorder has been adjusted to a definite amount as indicated on the voltmeter, the recorder is adjusted to indicate the corresponding power level by means of the "calibration" dial, which controls the gain of the a-c amplifier.

Uses of the Recorder

The uses of this recorder are very varied as can be judged from the following abbreviated list of applications. It may be used for obtaining:

1. Frequency-attenuation characteristics of filters. An example of this is shown in figure 13 which is the characteristic of a band-pass filter.
2. Frequency-attenuation characteristics of an entire radio set.
3. Frequency-attenuation characteristics of voice channels.
4. Frequency-attenuation characteristics of carrier channels.
5. Frequency-attenuation characteristics of transformers, loud speakers, amplifiers, etc.
6. Measurements of noise levels.
7. Power-level measurements of voice levels occurring in the output of a phonograph record, a radio program, etc. (figure 14).

Since the recorder slide-wire and pen are driven by a fair-size motor, control disks may be mounted on the slide-wire shaft and used for signaling or control purposes (that is, introducing additional attenuation into a filter or a channel to keep the total attenuation or power output within restricted limits).

The slide-wire motor may be used to drive the transmitter of a remote indicator or recorder and thus obtain two records at widely separated points.

Appendix

The Slide-Wire Attenuator

The equations developed here are useful in designing slide-wire attenuators.

If the total attenuation, the characteristic impedance, and the desired accuracy of the attenuator are known, the values of the shunt and series coils can be readily computed. Referring to figures 15*A* and 15*B*, let:

A = total attenuation in decibels
S = number of sections
Z_k = characteristic impedance of the attenuator
Z_b = impedance of each series coil
Z_a = impedance of first shunt coil
Z_t = terminating impedance
E_o = voltage output of one section
E_o' = voltage output along section
E_i = voltage input
n = fraction of a section; ratio of distance between adjacent shunt coil tap and contact to distance between shunt coils. Distances are measured in the output-input direction
n_{max} = value of n for which the attenuation error is maximum
D = attenuation error in decibels
D_{max} = maximum attenuation error in decibels

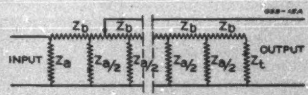

Figure 15A. Schematic diagram of the slide-wire attenuator

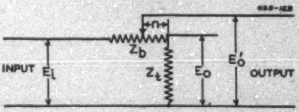

Figure 15B. One section of the slide-wire attenuator

Now the attenuation per section of a slide-wire attenuator is,[3]

$$-\frac{A}{S}=20\log\frac{E_o}{E_i} \tag{1}$$

(all logarithms in this paper are to the base 10).

But

$$\frac{E_o}{E_i}=\frac{Z_t}{Z_t+Z_b}$$

where

$$Z_t=\frac{Z_aZ_k}{Z_a+Z_k} \tag{2}$$

The characteristic impedance of a symmetrical π section attenuator is

$$Z_k=\sqrt{\frac{Z_a^2Z_b}{2Z_a+Z_b}} \tag{3}$$

Hence

$$Z_b = \frac{2Z_a Z_k^2}{Z_a^2 - Z_k^2} \tag{4}$$

therefore

$$\frac{E_o}{E_i} = \frac{Z_a - Z_k}{Z_a + Z_k} \tag{5}$$

and the attenuation per section can be written,

$$-\frac{A}{S} = 20 \log \frac{Z_a - Z_k}{Z_a + Z_k} \tag{6}$$

the total slide-wire resistance (R_s) is of course

$$R_s = SZ_b \tag{7}$$

If the impedances of the shunt and series coils of the attenuator are assumed to be pure resistances, their values may be obtained from equations 4 and 6 when the total attenuation, the characteristic impedance, and the number of sections are known. The first two are generally known, but the number of sections is not and must be determined from the accuracy requirements in accordance with the following method.

Since the values of the attenuation in decibels at successive shunt coils lie on a curve which is linear, but the variation in attenuation between shunt coils is not linear, the number of sections is determined by the allowable attenuation error of the attenuator. This error can be readily calculated and by using a sufficient number of sections, it can be made negligible.

Referring to figure 15*B*, the actual attenuation at a fractional position n is:

$$-\frac{A}{S}(\text{actual}) = 20 \log \frac{E_o'}{E_i} = 20 \log \left(\frac{Z_i + nZ_b}{Z_i + Z_b}\right)$$

$$= 20 \log \left(\frac{Z_a - Z_k + 2nZ_k}{Z_a + Z_k}\right)$$

(in terms of Z_a and Z_k)

but from (5)

$$Z_a = Z_k \left[\frac{1 + E_o/E_i}{1 - E_o/E_i}\right]$$

Which gives,

$$-\frac{A}{S}(\text{actual}) = 20 \log \left[n + (1-n)\frac{E_o}{E_i}\right]$$

or

$$-\frac{A}{S}(\text{actual}) = 20 \log \times \left[n + (1-n) \operatorname{antilog}\left(-\frac{A}{20S}\right)\right] \tag{8}$$

The desired attenuation is $(1-n)$ 20 log (E_o/E_i) or $-(1-n)A/S$.

The attenuation error in one section for a fractional position n is in decibels,

$$D = -(1-n)\frac{A}{S} - 20 \log \times \left[n + (1-n) \operatorname{antilog}\left(-\frac{A}{20S}\right)\right] \tag{9}$$

Therefore, the attenuation error of the slide-wire is independent of the characteristic impedance and dependent only on the decibel range and the number of sections (exclusive of frequency errors).

The point in each section of the slide-wire attenuator at which the error is greatest may be found by differentiating D with respect to n and equating the derivative to zero.

$$\frac{dD}{dn} = +\frac{A}{S} - \frac{20(\log \epsilon)\left[1 - \operatorname{antilog}\left(-\frac{A}{20S}\right)\right]}{n + (1-n) \operatorname{antilog}\left(-\frac{A}{20S}\right)\Big]}$$

hence

$$n_{\max} = +\frac{20S}{A} \log \epsilon - \frac{\operatorname{antilog}\left(-\frac{A}{20S}\right)}{1 - \operatorname{antilog}\left(-\frac{A}{20S}\right)} \tag{10}$$

When this value of $n_{\max}$ is substituted in equation 9, the maximum error ($D_{\max}$) is obtained.

The graphs of figure 9 show the location of the point in each attenuator section at which the attenuation error is greatest ($n_{\max}$) and the value of this error ($D_{\max}$) at every point in each section. If the value of S/A is greater than 1/4, the maximum error is small and occurs very close to the midpoint of each section.

Synchronizing Transients and Synchronizers for Large Machines

Synopsis: This paper reports an investigation of the transients accompanying synchronizing operations performed under practical conditions which include some departures from the ideal conditions as to voltage, phase position, and frequency of the incoming machine. A typical long-distance transmission system is selected for the study of the transients arising from the synchronizing of one of several similar units connected to the same sending-end bus. This problem reduces to that of a three-machine stability problem which is carried out with the aid of the a-c network calculator. The body of the paper shows the variations in initial and maximum "swing" currents, in voltage, in frequency, and in angular relations which may be produced by synchronizing under unfavorable conditions. The results of this study are then examined from the standpoint of automatic synchronizers and criteria for defining their performances are developed. The latter part of the paper includes a description of a new electronic type of automatic synchronizer. The operating features of this synchronizer, which have been installed on the more recent units of the Boulder Dam installation, are discussed.

Synchronizing Transients

IT IS a curious fact that the phenomena encountered in synchronizing operations have received scant attention in the technical literature even though the phenomena have been encountered ever since two synchronous machines were first operated in parallel, and even though a large number of synchronizing operations are performed every day. Possibly the explanation is due to two facts; first, that the ideal conditions introduce no disturbance, and, second, that the synchronizing transients are usually not large but for analysis require consideration as a stability problem of considerable complexity. A review of the synchronizing problem has become desirable because of the development of new types of automatic synchronizers and because of the progress in the analysis of system transients in connection with system stability. This study includes only those synchronizing operations for which the voltage, phase, and frequency conditions are matched before the connection is made; it does not include self-synchronizing methods.

The early synchronizing operations were performed manually and the large majority of them continue to be accomplished in this way even to the present day. The exacting requirements for a perfect synchronizing operation were, of course, not met initially. The first apparatus used to facilitate synchronizing consisted of lamps operated from the differential voltages of the machines to be synchronized. Lamps could indicate only the approximate relative phase position and frequency, and were incapable of showing whether the speed of the incoming machine should be raised or lowered. The introduction of the synchroscope by P. M. Lincoln marked an important step in the development of synchronizing equipment. The performance varied widely from installation to installation, being dependent upon the skill of the operator and upon the apparatus characteristics which permit accurate matching of the frequencies and the phase positions.

It was early recognized that ideal conditions for synchronizing produced no disturbance but that unfavorable conditions could produce a more severe disturbance than a dead short circuit at the machine terminals, particularly if the incoming machine were connected in parallel on the same bus with other units of much larger aggregate capacity. A number of schemes were proposed to minimize the bad effects of imperfect synchronizing. Most of these required the introduction of reactance in the circuit between the incoming machine and the remainder of the system. This introduction of reactance was also favorable from the standpoint of reducing the duty on circuit breakers but unfavorable from the standpoint of maintaining the machines in synchronism at times of disturbances. For that reason some of the schemes contemplated the introduction of reactance into the circuit during the synchronizing operation but with its removal after the operation was completed. One method occasionally used for accomplishing this result was to synchronize through a remotely connected unloaded transmission line.

The trend toward automatic equipment in recent years has expedited the development of automatic synchronizers. The advantages to be obtained from automatic synchronizing are: (1) the reduction of stress in the incoming machine, (2) the reduction of disturbance to the system, (3) the elimination of a requirement for special skill on the part of the operator or avoidance of delay in performing the operation, and (4) the ability to make consistent repetitive operations. The first automatic synchronizer in America was developed in 1906.

The synchronizing problem became of increasing importance and complexity as long-distance transmission became more extensive. This was due in part to the increased size of the machines and in part to the reduced reactance, a feature introduced to improve the transient stability of the longer transmission installations. Developments in stability also introduced the need for faster circuit breakers for disconnecting the faults encountered on such systems and thus to minimize the transient disturbances resulting therefrom. This process of speeding up circuit breakers has carried with it the speeding up of circuit closing. The shorter and more definite time for circuit closing is, of course, advantageous from the standpoint of synchronizing operations, whether performed manually or with the automatic equipment. However, some changes in the adjustment of automatic synchronizers may be required to take full advantage of higher circuit-closing speeds. The Boulder Dam installation is remarkable for the size of the units and the relatively low reactances which are employed. As a consequence, it became desirable to develop a new synchronizer especially designed to meet these exacting requirements of low stress under synchronizing operations, and to take advantage of faster circuit-closing speeds. This development provided the occasion for an analytical review of synchronizing transients taking advantage of the advances which have been made in recent years in the understanding of stability and other electromechanical transients on power systems.

Paper 40-26, recommended by the AIEE committee on automatic stations, and presented at the AIEE winter convention, New York, N. Y., January 22–26, 1940. Manuscript submitted November 20, 1939; made available for preprinting December 20, 1939; released for final publication February 28, 1940.

M—Incoming machine
T—Transformers

Synchronizing conditions may be analyzed in terms of three factors, namely, voltage magnitude, phase relation, and frequency of the incoming machine in comparison with the corresponding system quantities. Imperfect synchronizing will produce currents which exert momentary torques in connected machines. These synchronizing currents may conveniently be classified as (1) "initial" currents which are based on subtransient reactances and the corresponding internal voltages, and (2) "swing" currents which are based on transient reactances and corresponding internal voltages and which do not include the very quickly decaying components. A broad picture of the synchronizing phenomena may be obtained by calculation of these currents for a variety of synchronizing conditions on a typical long-distance transmission system with low-reactance generators.

Typical System Selected for Analysis

A typical transmission system, illustrated in figure 1, was selected for the study of synchronizing transients. In this figure the machines can conveniently be considered in three groups as follows:

1. Generator group, consisting of three units at the sending end.
2. Motor group, consisting of three motors of the same capacity, at the receiving end.
3. The incoming machine.

The transmission system is assumed to be carrying a motor load equal to the rating of the three generators. The incoming machine is assumed to be identical in characteristics to the other generators but of one-third the capacity of the generator or motor group. The system is assumed to be without losses and the voltages are to be maintained at equal values on the low-voltage sides of the transformers at the sending and receiving ends. Each machine is assumed to have an inertia constant[1] of five kilowatt seconds per kilovolt-ampere. This represents a somewhat higher than normal value for hydroelectric units but an average value for turbogenerator units.

The generators and motors are each assumed to have 20 per cent transient reactance and 15 per cent subtransient reactance. The equivalent reactance diagram of the system shown schematically in figure 1 is given in figure 2 using transient reactances which are required for swing calculations. The equivalent star diagram for the calculations of the initial symmetrical subtransient currents would be obtained by reducing the generator and motor branches in figure 2*a* from 20 to 15 per cent respectively, and reducing the incoming machine branch from 60 to 45 per cent.

A vector voltage diagram for the initial conditions of operation, that is, just prior to synchronizing, is shown in figure 3. The voltage of the incoming machine is plotted in this figure for a condition in which the incoming machine voltage, E_M, leads by a small angle the voltage E_{TS} of the system at the point at which the machine will be connected. The voltage E_{TS} is used as the reference voltage for defining the phase of the incoming machine. Different synchronizing conditions with respect to the phase of the incoming machine voltages are shown diagrammatically by the locus of E_M in figure 3. The case shown is that in which the incoming machine voltage is exactly equal in magnitude to the system voltage. The reference voltage will normally have a phase position closer to that of the generators on the same bus than to that of the receiver machines. It will also be noted from figure 2 that the incoming machine can interchange very much larger amounts of power with one group of machines than with the other, the interchange being greater with the generators on the same bus.

The *initial symmetrical currents* caused by synchronizing depend upon the subtransient reactances and internal voltages of the system, and upon the relative phase position of the incoming machine. The convenient reference for that voltage is the voltage of the system at the point to which the incoming machine is to be connected. The calculated values for these instantaneous synchronizing currents are given in figure 4, for three values of incoming machine voltage equal to 92, 100, and 108 per cent of the system voltage at the point of connection. It will be noted that the initial currents are affected more by the phase position of the incoming machine than by the normal variations in the magnitude of incoming machine voltage. When synchronizing with zero difference in phase, the magnitude of the internal voltage is of some importance, and the currents are of zero magnitude only when the incoming voltage is exactly equal to the system voltage. For the range of

Table I. Summary of Transient Conditions for Synchronizing the System of Figure 1

	Initial Conditions For Incoming Machine				
Item	Voltage (Per Cent)	Frequency (Per Cent)	Angle (Deg)	Sending-End Terminal Voltage Minimum (Per Cent)	Receiving-End Frequency, Maximum or Minimum (Per Cent)
1	100	100	+30	96	99.8
2	100	100	0	100	100.0
3	100	100	−30	92	100.16
4	100	101	+30	92	99.75
5	100	101	0	96.5	99.77
6	100	101	−30	95	100.03
7	100	99	+30	95	99.98
8	100	99	0	94	100.3
9	100	99	−30	92	100.4

conditions, there is relatively little difference between these currents for these three values of incoming machine voltage, the maximum difference being less than 40 per cent of rated current. For this reason it is considered adequate to study the influence of the other variables in the problem only for the conditions in which the incoming machine voltage equals the system voltage.

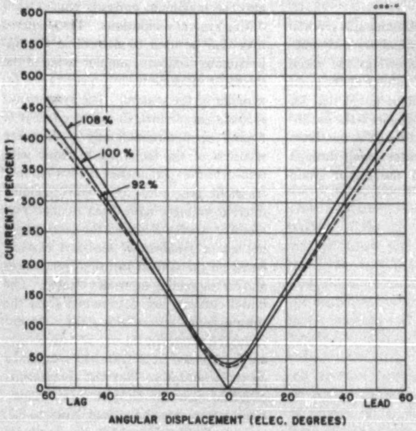

Figure 4. Instantaneous symmetrical synchronizing currents in the incoming machine, plotted for three ratios of incoming voltage to system voltage—based on subtransient reactances

Transient conditions may be more severe than the initial conditions in regard to torque and current stresses and thus it becomes necessary to examine "swing" curves to determine the maximum conditions. For example, for the condition of synchronizing with the voltage magnitude and phase position of the incoming machine equal to the corresponding system quantities there is no disturbance initially but there will be one at a subsequent time if the frequency of the incoming machine is different from that of the system. A greater disturbance will be experienced if the connection is made when a difference in phase also exists. In order to provide a general picture of the phenomena, it has been found convenient to analyze the transient conditions as outlined in table I, including three frequencies of the incoming machine of 101, 100, and 99 per cent of the system frequency and including three phase positions of 30 degrees leading, 0 degrees, and 30 degrees lagging. These deviations of one per cent in frequency and 30 degrees in phase position, while representing relatively large departures from the standpoint of proper synchronizing, do assist in giving a broad picture of the phenomena and do provide a basis for general curves passing through points representing small deviations. Leaving out item 2 of table I for the ideal synchronizing condition, there remain eight conditions which may be grouped in four pairs as follows: items 1 and 3, 4 and 9, 5 and 8, 6 and 7. For each pair of conditions the magnitudes of the transient disturbances are the same or substantially the same, but the initial directions of movement are opposite. This observation greatly simplifies the analysis of the many conditions to be examined. It is to be noted that the conditions outlined in table I do not include variation in voltage of the incoming machine with respect to system voltage. The incoming machine voltage has been taken as equal to the system voltage for the reasons previously discussed.

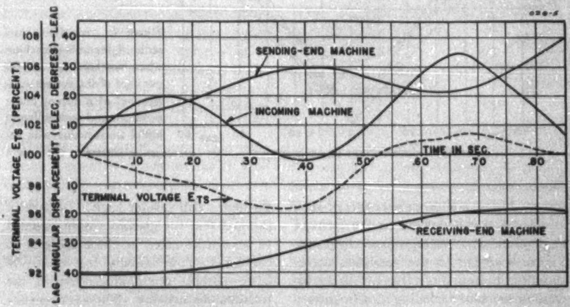

Figure 5. Time-angle relations for the system of figure 1 with the incoming machine synchronized at zero phase position and at 101 per cent frequency. The variations in the terminal voltage at the sending end are also shown

The preferred method of examining the transient disturbances due to imperfect synchronizing is the step-by-step method using the a-c network calculator as employed in the analysis of three-machine stability problems.[1] By this method the problem is considered as one in dynamic equilibrium and the position of each rotor is computed on the basis of its inertia and its mechanical and its electrical inputs or outputs, the electrical conditions being computed on the basis of constant internal voltages acting through known system reactances. By using the equivalent circuit of figure 2*b*, the three-machine stability problem may be analyzed as three problems each involving one reactance and two sources of electromotive force. Figure 5 shows the results of such step-by-step calculations in the form of angle-time and voltage-time diagrams. Figure 5 applies to the condition corresponding to item 5 of table I, with the incoming machine traveling at a frequency one per cent above that of the system but synchronized with the phase of the incoming-machine voltage identical with that of the system voltage at the point of connection. In this discussion of transients the phase position of synchronizing is given in terms of the angle by which the incoming-machine voltage leads or lags the initial position of the system voltage at the point of connection. It will be noted that for the condition shown in figure 5 the incoming machine swings through a relatively large angle, the generator group through a smaller angle, and the motor group through a still smaller angle. Because of the fact that the machines were assumed to be synchronized in phase there is no current to flow initially but relatively large currents are produced during the transient disturbance. These transient or "swing" currents may be estimated from the relative phase positions of the different machines as shown in figure 5 and the internal voltages and reactances of the system as discussed subsequently. It may be pointed out that if the synchronizing operation were performed with the incoming machine operating at 99 per cent of system frequency the transient disturbance would be similar except that the initial movement of all machines would be in directions opposite to those shown in figure 5, but the amplitudes would be substantially the same. If the incoming machine were synchronized out of phase but with the same differential frequency the oscillations would be of increased amplitude as shown in figure 6 which covers the conditions of synchronizing at 30 degrees lagging and a frequency of 99 per cent.

---

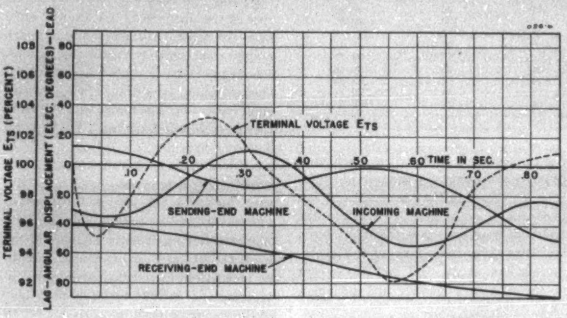

Figure 6. Time-angle relations for the system of figure 1 with the incoming machine synchronized at 30 degrees lagging and at 99 per cent frequency. The variations in the terminal voltage at the sending end are also shown

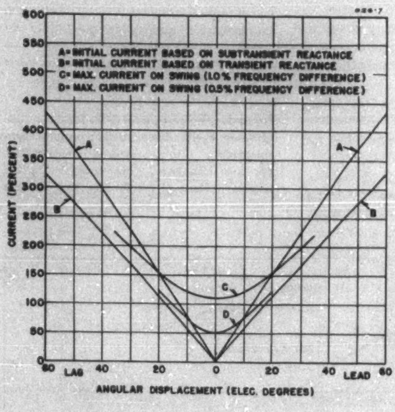

Figure 7. Maximum currents of incoming machine when synchronized at 100 per cent of the system voltage but at different phase positions and with different initial frequencies with respect to the system

A very useful diagram for studying transient conditions is shown in figure 7. This figure shows the initial currents and also the maximum currents encountered during system oscillations. These curves may also be used to determine the approximate maximum angular swing of the incoming machine with respect to the remainder of the system. The *symmetrical subtransient currents*, shown by curve *A* of figure 7, are determined only by the phase relations of the incoming machine with respect to the system since the system subtransient reactances and corresponding internal voltages have been defined previously. Curve *B* shows the corresponding set of *symmetrical transient currents* based on the system transient reactances and corresponding internal voltages. The initial currents are determined from the subtransient reactances; the current values encountered during system swings are determined from transient reactances on the assumption that the components of initial currents, subject to the short-time decrements, have had time to become negligible. These transient currents may, therefore, be related to the angular displacement curves if the internal voltages, are maintained constant by voltage regulators. The omission of voltage regulators would, however, not affect the phenomena in any important way. In the calculations the effects of losses have been neglected so that the system tends to oscillate equally in both directions about its mean point.

Consider now in detail the explanation of the use of figure 7 to determine the initial and maximum swing currents and angular displacements for different initial conditions of synchronizing. Consider first the case in which the system is synchronized at an angle of 30 degrees leading (or lagging). The initial symmetrical subtransient current is seen to be approximately 225 per cent of the rated current for the machine as read on curve *A* for the angle of 30 degrees. If the incoming machine were operating at a frequency equal to that of the system, the incoming machine would oscillate from 30 degrees lead to approximately 30 degrees lag and at that point it would draw a swing current equal to 170 per cent of its own rating as read from curve *B* at 30 degrees lag.

Consider next the case in which the system is synchronized with zero difference in phase but with a frequency difference of one per cent as given by figure 5. In this case the initial currents are zero as shown by curve *A* of figure 7 for the angle of 0 degrees. There will, however, be a transient oscillation which quickly produces a maximum angular displacement of 20 degrees as shown in figure 5. Curve *C* has been plotted for the purpose of giving these maximum swing currents and maximum angular displacements for synchronizing under one condition of frequency difference. The maximum swing current for the case considered in figure 5 is obtained by entering the frequency-difference curve *C* at the initial synchronizing angle, zero in this case. This gives a maximum swing current of 120 per cent. This value of current is identical with that shown by curve *B* based on transient reactances with an angular displacement of approximately 20 degrees. Curve *D*, calculated by an approximate method, has been added to indicate the nature of the family of curves similar to curve *C*. Thus, curves *C* and *D* may be used to give the maximum swing currents and the maximum angular displacements for the initial outward swing and return. Subsequent swings are not considered because of the damping due to the system losses.

Considering now the more complicated case of figure 6 for which the incoming machine is synchronized at an angle of 30 degrees lagging with the machine operating at a frequency of 99 per cent of the system. In this case the initial current is approximately 220 per cent as obtained from curve *A* at the angle of 30 degrees. The maximum swing current is given by curve *C* at the angle of 30 degrees and the value is 200 per cent. This value of transient current corresponds to a maximum displacement of 36 degrees which is the value on curve *B* which gives the same current of 200 per cent. This maximum angular displacement of 36 degrees is shown on figure 6 as occurring very shortly after synchronizing. Approximately the same angular displacement would be encountered if the system were synchronized at 30 degrees leading, with a frequency difference of 99 per cent. In this case the effect of phase position and initial frequency difference would be in such a direction as to cumulate the oscillations and thus would overshoot from the initial angle of 30 degrees on one side of the reference angle and swing to a maximum of about 36 degrees on the other side. Similar swings would be encountered for the other pair of conditions with the same angular displacements and the same frequency difference but with a different sign of the angle or sign of the frequency difference.

There is another effect that requires consideration and a certain amount of explanation. Synchronizing action may produce a permanent change in the phase positions of the system with respect to their original positions. If the incoming machine were synchronized under ideal conditions there would be no tendency for the phase position of the entire system to change. If, however, the incoming machine were synchronized at 0 degrees but with a frequency of 101 per cent of that of the system, the incoming machine would give up energy in order to synchronize and the system would correspondingly absorb energy and shift the absolute phase position in a forward direction as shown in figure 5. A similar effect is produced when machines traveling at the same frequency are synchronized out of phase. If the incoming machine has a voltage whose phase position is leading that of the system at the point of connection, the synchronizing action will cause the incoming machine to drop back in phase position and the system to move forward in phase position. If the machines were synchronized with the incoming machine lagging that of the system, the shift in absolute phase position would, of course, be in the opposite direction. Both effects are present when the system is synchronized under conditions including both angular difference and phase difference. These effects may tend to augment each other as shown in figure 6 or to oppose each other as would occur if the frequency of the incoming machine were one per cent above normal instead of one per cent below normal.

The change of the absolute phase position as a result of synchronizing is, generally, of little importance from an operating standpoint. This is due to the fact that usually the various machines connected to a system can follow it. However, in some cases, because of a relatively high product of inertia and reactance of the tie connection, some of the smaller machines may not be capable of quickly following a system disturbance. Under these conditions, synchronizing at a leading angle when the frequency is less than normal or at a lagging angle when the frequency is above normal may be advantageous. These phenomena explain certain practical operating conditions that have been observed in which two disturbances, produced by synchronizing, appear to be of equal magnitude at some parts of the system but of radically different magnitude at other parts. However, it is not considered advantageous to modify the usual synchronizing procedure since that would increase the disturbances for the main machines, although reducing them for the others.

The effects of various synchronizing conditions on the sending-end bus voltages are listed in table I. The variations in voltage at the receiving bus will be only a fraction of the minimum values tabulated. In some special applications the rapid variation in velocity or frequency in cycles per second is of importance. For this reason, the variations in frequency of the receiving-end machines are also given in table I. In connection with the variation in voltage and in frequency, it is to be recognized that these synchronizing conditions include wide departures from usual or proper synchronizing.

Synchronizing under conditions producing transient currents with a d-c component will cause pulsating rotor currents and pulsating torques. These torques are responsible for the low-frequency vibrations of machines during synchronizing causing these machines to "grunt". This circumstance provides another reason for securing accurate control of voltage difference and particularly of phase difference. If a machine rotor has a natural frequency close to fundamental frequency of the system, there will be a tendency to augment the oscillation due to pulsating rotor currents. Ordinarily, the natural frequency of machine rotors will be well below the generated frequency, particularly for hydro machines.

Requirements for Good Synchronizing

The relative importance of the variations in voltage difference, frequency difference, and phase difference, that are likely to be encountered in commercial installations will now be considered.[3,4] The voltages of the incoming and running machines are usually under the control of voltage regulators and the voltage difference for normal conditions will be less than five per cent which can readily be reduced by manual adjustments. The frequency of the incoming machine is under the control of a governor with speed matcher and the frequency difference may range from 0.025 to 0.10 cycles per second for large machines. For smaller machines this range should be increased to 0.3 cycle per second with the reservation that some small machines are too erratic for good synchronizing. The range of frequency difference may also be expressed in terms of the revolutions of the synchroscope and the corresponding figures are 40 to 10 seconds per revolution for large machines and the range increased to 3 seconds per revolution for small machines. A phase difference of five degrees represents a limit which is as difficult to obtain as the limits given for the other factors.

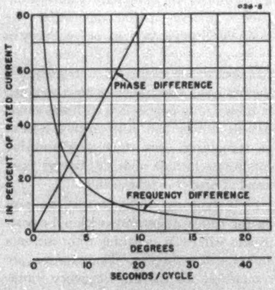

Figure 8. Comparison of the effects of frequency difference and phase difference on magnitude of inrush currents

The magnitude of current in the incoming machine may be taken as a measure of the disturbance produced by synchronizing action. Using this criterion, it is an easy matter to compare the relative importance of the differences due to voltage, frequency, and phase angle. From figure 4 it will be seen that for the system of figure 1, an eight per cent difference in voltage will cause a current in the incoming machine equal to 40 per cent of its rating when synchronized under ideal conditions as to frequency and phase difference. This figure also shows that the effect of voltage difference upon the synchronizing current is relatively more important for small than for large angular differences. In view of the fact that voltage regulators keep the voltage difference within five per cent, it is apparent that the effect of voltage difference under practical operating conditions is relatively unimportant in comparison with the other factors.

In considering the relative importance of frequency difference and phase difference, it is convenient to use the data of figure 7 but replotted in the form shown in figure 8. This curve shows that synchronizing at zero phase difference but with a frequency difference of three seconds per cycle will produce a current in the incoming machine of about 50 per cent of its rating. This value of current would be produced by synchronizing with zero difference in frequency but with a six-degree difference in phase. From this, it becomes evident that, within the normal range of control, the effect of frequency difference is less important than that of phase-angle error. The effects of losses, including induction-motor action, will further minimize the oscillations and swing-current magnitudes. The variation of phase difference arises principally from the change in angle which takes place during the time that is required for the synchronizing breaker to close. For example, on the system which has been considered, the frequency difference of 0.16 cycle per second or 6.0 seconds per revolution of the synchroscope, the system will shift 30 degrees in phase position during the time of 0.5 second, which is not an unreasonably long closing time for a synchronizing breaker. It is apparent, therefore, that quite accurate compensation for frequency difference is required. In other words, if the synchronizing breaker is actually closed at zero phase position the frequency difference normally encountered under synchronizing conditions on commercial systems will not introduce disturbances of important magnitude.

The discussion which has been given in the paper applies principally to the typical system selected for study. It should, however, be pointed out that with lower-reactance machines or with greater capacity on the bus, the relative importance of phase difference in synchronizing is increased. Similarly, if the inertia of the incoming machine is increased, the effect of frequency difference in synchronizing is increased. The system selected for study is believed to be representative of the more severe conditions from the standpoint of synchronizing currents and disturbance to the incoming machines.

The essential features for automatic synchronizers may be stated as requiring the following:

1. **A phase advance element which compensates for the time required to close the synchronizing circuit breaker, this element being properly responsive to change in frequency difference.**

2. **A beat-frequency characteristic which prevents operation of the synchronizer if the frequency of the incoming machine differs too widely from that of the system.**

3. **A voltage-difference element which prevents operation of the synchronizer if the voltage difference is excessive.**

The beat-frequency characteristic and the voltage difference element prevent operation of the synchronizer under conditions which might produce doubtful synchronizing or which might be beyond the range of the compensating features provided in the phase-advance element. It is, of course, necessary that the various elements perform their functions correctly for the range of voltage and frequency variations that are encountered in practice. The phase-advance element must be adjustable for the time range required for closing the synchronizing breakers. The beat-frequency characteristic must also be adjustable to suit the range required on the particular system.

Description of Electronic Synchronizer

Automatic synchronizers have been on the market for several years.[2,3,4] Previous types have employed electrically interlocked relays which operate each time the phase angle between the machine and line voltages becomes zero. These automatic synchronizers have given excellent service in a variety of applications. However, it has become evident that faster and more accurate synchronizing could be obtained if the interlocking relays were eliminated and their functions performed by electronic means. In order to eliminate all moving parts except the first breaker-closing relay, an "all-electronic" synchronizer was developed.

The internal circuit of this synchronizer comprises two thyratron tubes, transformers, and several rectifiers, capacitors, resistors, and a breaker-closing relay. Each rectifier is provided with a smoothing capacitor and resistor. Voltage-checking relays, apart from the automatic synchronizer, prevent synchronizing operations until contact I is closed to denote that the machine and line voltages are approximately equal.

Figure 9*a* illustrates the two thyratron tubes, T_1 and T_2, which are electrically interlocked so that relay I will become energized to close the circuit breaker only when both tubes pass current in series from rectifier X_8. The tube-interlocking circuit is arranged to prevent operation of tube T_1 if tube T_2 has already started to pass current. Current flowing through resistor R_8 from rectifier X_7 causes the voltage across resistor R_8 to become suffi-

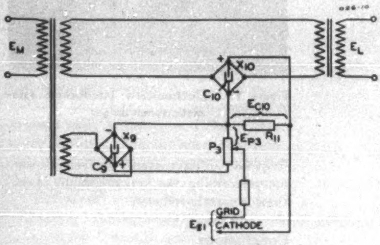
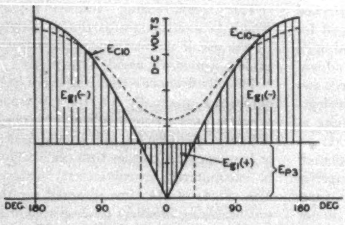
ciently negative as to bias tube T_1 and prevent its operation.

The operation of these tubes will respond to the grid-control voltages E_{g1} and E_{g2}. If these grid-control voltages have frequency-difference and phase-angle characteristics as shown in figure 9*b*, tubes T_1 and T_2 will operate to close relay I only when the frequency difference is less than F_1. When the frequency difference exceeds F_1, tube T_2 operates before the phase angle α_1 is reduced to that for which tube T_1 is set to operate. Consequently, relay I cannot operate.



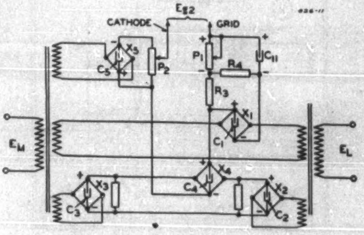
(a) SCHEMATIC DIAGRAM



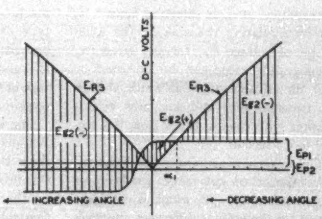
(b) GRID VOLTAGE PHASE DIFFERENCE CHARACTERISTICS

Figure 10 (left). Grid-control circuit for tube T_1

Figure 10*a* illustrates the method for obtaining grid-control voltage E_{g1} for tube T_1. A constant d-c potential E_{P3} is obtained from rectifier X_9. A variable d-c potential E_{C10} is obtained from the "beat-frequency" voltage rectifier X_{10}. By varying the adjustment of rheostat P_3, the grid voltage E_{g1} can be made to become positive at a definite angle of advance, as indicated by the curves in figure 10*b*. This angle of advance is practically independent of the frequency difference so long as it does not exceed the usual synchronizing limits of one-fourth to one-third cycle. If the frequency difference is high, capacitor C_{10} introduces a delaying action so that voltage E_{C10} does not become zero when the phase angle is zero but follows the dotted line shown in figure 10*b*. This characteristic prevents synchronizing when the frequency difference is too high. However, it does not affect the accuracy of synchronizing at the normal synchronizing frequency differences.



(a) SCHEMATIC DIAGRAM



(b) GRID VOLTAGE PHASE DIFFERENCE CHARACTERISTICS

Figure 11 (right). Grid-control circuit for tube T_2

Figure 11*a* illustrates the method for obtaining grid-control voltage E_{g2} for tube T_2. Voltage E_{g2} consists of four components, E_{P2}, E_{R3}, E_{C4}, and E_{P1}. Voltage E_{P2} is a constant value taken from rheostat P_2. Voltage E_{R3} is obtained from the "beat-frequency" voltage rectifier X_1. This is a variable voltage that is high for large phase angles, low for small phase angles, and zero only when the machine and line voltages are exactly equal and exactly in phase. Voltage E_{C4} is taken from rectifier X_2 and X_3 through rectifier X_4 to obtain compensation against differences between the machine and line alternating-voltage magnitudes, within the range set by an external over-all voltage difference checking relay.

Rheostat P_1 and capacitor C_{11} are connected across resistor R_4 which receives voltage from the "beat-frequency" voltage rectifier X_1. When the phase angle decreases from 180 degrees toward zero, capacitor C_{11} discharges through rheostat P_1. This produces a voltage drop E_{P1} which is approximately proportional to the frequency difference and which has a polarity as indicated in figure 11, with the result that the grid of tube T_2 tends to become more positive if the frequency difference is high.

The curves in figure 11*b* show the various component voltages E_{P2}, E_{R3}, and E_{P1}. Voltage E_{C4} is not shown for it is assumed that the machine and line voltages are equal in magnitude. E_{B3} is highly negative at 90 degrees phase angle and decreases to zero at zero phase angle. Voltage E_{P2} is adjusted so that when E_{P1} is zero (that is, when the frequency difference is zero), the grid voltage E_{g2} becomes zero at approximately two degrees angle. As the frequency difference is increased, voltage E_{P1} increases proportionally so that the grid voltage E_{g2} becomes zero at an advanced phase angle, for example, at α_1 as shown in figure 11*b*. By manipulating rheostat P_1 the magnitude of voltage E_{P1}, for any given frequency difference, can be adjusted so that the advance angle at which voltage E_{g2} becomes zero will suit any circuit breaker with closing times from 0.3 second to 0.8 second.

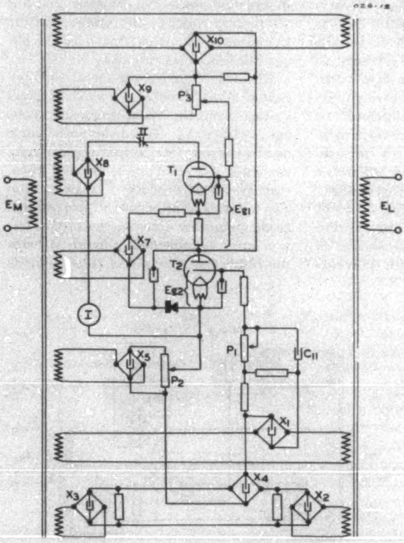


Figure 12. Schematic diagram for complete electronic synchronizer

The internal diagram for the electronically-interlocked automatic synchronizer is shown in figure 12, which is complete except for the voltage difference checking and other auxiliary relays. A photograph of this synchronizer is shown in figure 13. The phase advance and lockout frequency-difference features are all obtained by interlocking of the vacuum-tube grid control and plate circuits. The breaker-closing relay which responds to the interlocked tube action is mounted in the synchronizer case.

Operating Experience

The generators at Boulder power plant are all synchronized by automatic means. This installation now includes a total of 11 units of which 8 are rated 82,500 kva, one 40,000 kva, and 2 station service units 3,500 kva each. The interlocked-relay type of synchronizer[3] was included with the original installation and has given good service in synchronizing these machines. The electronically-interlocked type of synchronizer was developed for use with the more recently installed units *A*-6 and *A*-7 in order to take full advantage of the fast breaker closing speeds and to provide more accurate synchronizing.

For synchronizing the larger units at Boulder power plant, operating results show that the electronically interlocked synchronizer performance is far superior to that of the interlocked-relay type. Control-battery voltage variations do not affect accuracy of the synchronizer because the plate and grid control circuits are all taken from the incoming generator potential which is under control of the voltage regulator, and reaches a constant normal value before the synchronizer becomes operative. The synchronizing performance is more consistently accurate because the electronic interlocking feature is co-ordinated with the actual speed of circuit breakers involved with the result that the current swings are reduced. Of equal importance to the peace of mind of the operating personnel is the relatively smooth synchronizing of the incoming machine and the almost complete elimination of "grunt" as the generator circuit is closed. Small differences in alternating voltage between generator and bus do not prevent breaker closure at the very low values of frequency difference and the over-all time for performing the synchronizing operations is greatly reduced.

Figure 13. Electronically interlocked automatic synchronizer

Conclusions

The synchronizing transients may readily be analyzed for particular systems by the use of the methods applied to the typical system discussed in the paper.

The disturbances resulting from synchronizing manually or by automatic synchronizers are more affected by phase difference than by the voltage differences or frequency differences that are likely to be encountered on commercial systems. The effects of the time required for the synchronizing breakers to close appear as differences in phase and may be compensated for by adjustments responsive to the frequency difference.

The electronic synchronizer described in the paper permits taking advantage of faster circuit-breaker closing speeds and provides more accurate synchronizing than the previous equipment with mechanical interlocking relays.

Analysis of Transient Voltages in Networks

P. L. BELLASCHI
FELLOW AIEE

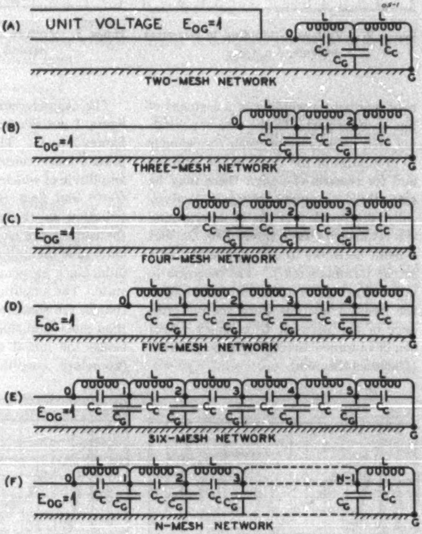
A. J. PALERMO
ASSOCIATE AIEE

IMPORTANT contributions on transient phenomena have appeared in the technical literature during the past two decades. Circuit analysis has contributed materially to the present-day knowledge resulting from studies of the following major engineering problems:[1–6] transient voltages in transformer, generator, and other apparatus windings due to surges originating from lightning; traveling waves and switching phenomena on lines and cables; recovery voltages across terminals of circuit breakers and protective devices as affected by the circuit; response of devices and circuits in measuring voltages and currents applied in impulse and short-circuit testing; and others.

These and other contributions on transient phenomena were made possible in a large measure through the development and application of the operational calculus.[7–13] The experimental aid afforded by the cathode-ray oscillograph and from other suitable means of measurement and testing has been invaluable in itself and, furthermore, it has in turn stimulated markedly the analytical work. Even within the field here considered, new engineering problems or the extending of the past studies into greater detail will require further analytical work. It is apparent that the need is arising to unify the various analyses and corresponding circuits into a more closely correlated whole. Should this process be carried out to its logical end, this branch of the engineering art would become better integrated; at the same time, it is expected that it would be extended in scope and also simplified.

Recognizing this need and bearing in mind the application to engineering, the writers have undertaken the analytical work in this paper. Mathematical processes are used, yet the physical approach is followed as much as possible. The practical advantages in guiding the mathematical solution in terms of physical concepts and of the underlying physical phenomena will become more apparent from the analysis and the accompanying figures. Likewise, efforts were directed to securing results with a minimum of mathematical encumbrance. To this end, the operational calculus was employed. The paper presents rational processes that have been developed and effectively applied in the analysis. These methods indicate the possibilities toward simplification and a more comprehensive approach to the problems requiring circuit analysis.

Figure 1. Symmetrical lumped networks



Symmetrical Lumped Networks

Many engineering problems requiring analysis are effectively approached through the simplification of the circuit into an equivalent network of finite meshes, each mesh generally consisting of two or more lumped parameters. Figure 1 shows a type of networks commonly encountered. These consist of series inductances (L), capacitance to ground (C_G) from each of the common points joining the inductances, and self-capacitance (C_C) across each inductance. These symmetrical lumped networks

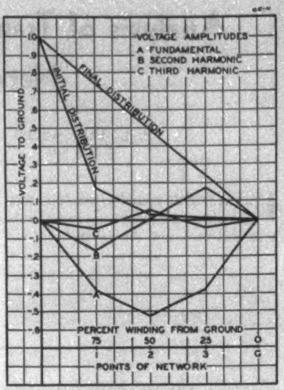

Figure 4. Voltage distribution in four-mesh network, $C_G = 4C_C$

may represent a winding or a segment of line or other part. In the case of a winding each inductance or mesh corresponds to groupings of the turns of the winding and for reasons of design there may be two, three, or more groups. Analytically, the problem is one of determining the response of two, three, four. . . and n-mesh networks to unit applied voltage at the terminals (OG). The response to unit voltage (Heaviside unit function) is the basis of analysis since the performance of the network to complex waves can be obtained directly by superposition (Duhamel theorem).

The characteristics of the networks in figure 1 are illustrated in the curves of figures 2 to 11. The response to unit applied voltage consists of oscillations, the amplitude of which depends on the initial ($t=0$) and final ($t \rightarrow \infty$) voltage distribution in the network. Physically, the capacitance elements of the network determine the initial distribution and the inductance elements the final or steady state. The amplitudes of the oscillations, that is, the space waves shown for $t=0$, thus must sum up to the difference between the initial and final distribution (boundary conditions). As illustrated in the figures, the greater this difference is, the greater become the amplitudes. In the analysis, the amplitudes of the oscillations are essentially determined from the boundary conditions through the Fourier process which in operational calculus is inherently performed in the derivation of the solution (appendix I).

For symmetrical networks each space wave is distributed symmetrically between ends, from line to ground, the amplitude being highest for the fundamental and correspondingly smaller for the "second", "third", and higher harmonics. The periods (time constants) of the oscilla-

tions naturally depend solely on the circuit parameters L, C_G, and C_C, the higher the order of the harmonic, the shorter the period but not in simple arithmetical relation. The total number of oscillations is $N-1$ where N is the number of meshes of the network. Thus each of the space waves oscillates at its natural period about the zero voltage axis, and, to determine the voltage distribution in the network at any time, the space waves at that instant are combined with the steady state.

A simplification in the analysis became apparent from physical considerations of the symmetrical progression of the network (figure 1) from two to three meshes, three to four, etc., which suggested a pattern of the operational expressions. This pattern can be set down completely for a network of any number of meshes when the operator for the two-mesh network is known; as follows:

(1) 1
(2) $\alpha+2$
(3) $\alpha^2+4\alpha+3$
(4) $\alpha^3+6\alpha^2+10\alpha+4$
(5) $\alpha^4+8\alpha^3+21\alpha^2+20\alpha+5$
(6) $\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6$
(7) etc.

where the operator alpha (α) is the ratio of the operational impedances of the series (Z_S) and the shunt (Z_G) elements of the mesh, that is, $Z_S/Z_G=C_GLp^2+(C_CLp^2+1)$ (appendix I).

To illustrate the analysis, for the six-mesh network, the voltages are written immediately in operational form:

$$e_{1G}=\frac{\alpha^4+8\alpha^3+21\alpha^2+20\alpha+5}{\alpha^5+10\alpha^4+36\alpha^3+56\alpha^2+35\alpha+6}$$

$$e_{2G}=\frac{\text{operator }4}{\text{operator }6}$$

etc.

These operational expressions are expanded into partial fractions of alpha (α). The operational terms then are in a form recognizable for conversion and the solution is effected. As an example:

$$e_{1G}=\frac{1/12}{\alpha+2-\sqrt{3}}+\frac{1/4}{\alpha+1}+\frac{1/3}{\alpha+2}+\frac{1/4}{\alpha+3}+\frac{1/12}{\alpha+2+\sqrt{3}}$$

$$e_{1G}=A_0-A_1\cos w_1t-A_2\cos w_2t-A_3\times\cos w_3t-A_4\cos w_4t-A_5\cos w_5t$$

where the specific values for the coefficients and the periods ($T=2\pi/w$) are given in appendix I.

The solution for e_{2G} and e_{3G} are similar expressions, which are readily obtained. The voltages e_{4G} and e_{5G} are apparent from the symmetry of the space waves (see figures 6 and 11).

The periods of oscillation inherently are established from the space wave distribution in relation to the elements of the network. A few examples will illustrate this physically fundamental relationship. For the fundamental of the two-mesh network, the "second" harmonic of the four-mesh, the "third" harmonic of the six-mesh, etc., the space wave rises from zero to maximum as a straight line and recedes back to zero in the same way. It is apparent from the space-wave distribution that the parallel elements L, C_C of the first leg oscillate with the three elements C_G, L, C_C of the second part. Thus, the effective inductance is $^1/_2L$ while the capacitances add together in determining the period, that is, $T=2\pi\sqrt{\frac{L}{2}(C_G+2C_C)}$. In the case of the fundamental of the three-mesh network, the "second" harmonic of the six-mesh, etc., the voltage of the space wave between points 1 and 2 of the network is zero and therefore the period in this case is determined simply from L, C_C in series with C_G, that is, $T=2\pi\sqrt{L(C_G+C_C)}$. For the "second"

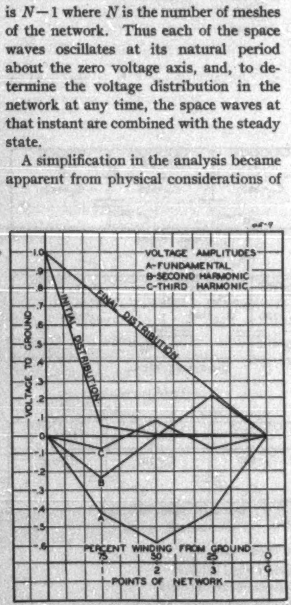

Figure 9. Voltage distribution in four-mesh network, $C_G=16C_C$

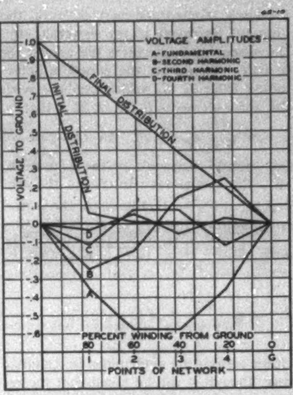

Figure 10. Voltage distribution in five-mesh network, $C_G=16C_C$

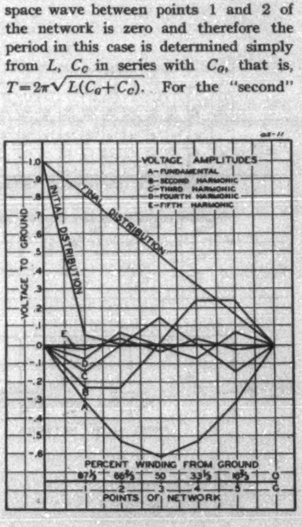

Figure 11. Voltage distribution in six-mesh network, $C_G=16C_C$

harmonic of the three-mesh network, the "fourth" harmonic of the six-mesh, etc., the space wave intersects the second leg in half. Therefore, the period is determined from L, C_C which oscillate with the three elements C_G, $L/2$, $2C_C$, that is, $T=2\pi\sqrt{\frac{L}{3}}(C_G+3C_C)$. In the case of the "third" harmonic of the four-mesh, etc., the space wave intersects the second leg at $(\sqrt{2}-1)$, therefore, the period is determined from L, C_C in combination with C_G, $\frac{L}{1+\sqrt{2}}$, $(1+\sqrt{2})C_C$, that is,

$$T=2\pi\sqrt{\frac{L}{2+\sqrt{2}}(C_G+[2+\sqrt{2}]C_C)}$$

Other periods are determined in a similar way, though it will be noted that the relation becomes complex in the measure that the space waves assume more complex geometrical forms.

Comparison of Uniformly Distributed and Lumped Networks

As the meshes increase in number, the network approaches uniform distribution. The solution for the uniformly distributed or infinite-mesh network is readily obtained from Heaviside expansion theorem (appendix II). The characteristics of this network are illustrated in figure 12. These consist of sinusoidal space waves.

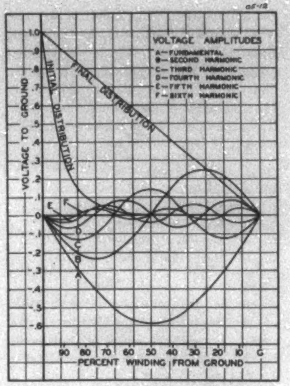

Figure 12. Voltage distribution in uniformly distributed network, $N\sqrt{\frac{C_1}{C_2}}=12$

A comparison of figures 2 to 11 with figure 12 shows the extent that a finite-mesh network approaches the uniformly distributed network. For example, the space wave of the fundamental for the six-mesh network attains a form and amplitude closely alike to the fundamental for the distributed network. The "second" harmonic is trapezoidal, the "third" harmonic triangular, etc., that is, the approach diminishes with the increasing order of the period.

The uniformly distributed, the six-mesh, and the three-mesh networks are shown together in figure 13 for the purpose of comparison. The basis is as follows: the total inductance, the total ground capacitance, and the total series capacitance (between the two ends), each is the same for each of the three networks. A value of the ratio of total ground to series capacitance has been selected which is representative in practical application, that is, $\sqrt{(C_1/C_2)N^2}=12$.

The amplitudes of the oscillations for the three networks are:

	Distributed Network (Figure 12)	Six-Mesh Network (Figure 6)	Three-Mesh Network (Figure 8)
Fundamental	0.59	0.58	0.47
Second harmonic	0.24	0.20	0.14
Third harmonic	0.13	0.11	
Fourth harmonic	0.07	0.05	
Fifth harmonic	0.04	0.02	
...	...		

In comparing the periods, let $T_k=\frac{2\pi}{\delta}\times\sqrt{(L_1C_1)N^2}$; where L_1N is the total in-

(*C*)—Mutual inductances network
Capacitances are in micromicrofarads and inductances in henrys

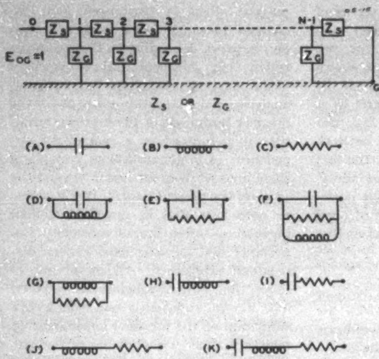

Figure 15 (left). Symmetrical lumped networks—generalized

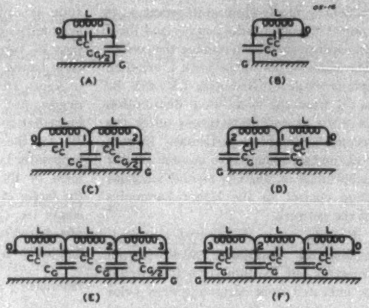

Figure 16. Ungrounded symmetrical lumped networks

ductance, C_1N the total ground capacitance, δ a numerical factor, while subscript k denotes the harmonic. The values of δ corresponding to the periods for the three networks are tabulated as follows:

	Distributed Network	Six-Mesh Network	Three-Mesh Network
Fundamental	3.04	3	2.91
Second harmonic	5.56	5.36	4.76
Third harmonic	7.40	6.93	
Fourth harmonic	8.65	7.85	
Fifth harmonic	9.52	8.33	
Sixth harmonic	10.12		
...	...		

The amplitudes for the distributed and the six-mesh networks are in generally good agreement. For practical purposes, for these two networks, it will be noted that the corresponding periods are also in quite close agreement. The comparison points out that the finite-mesh networks can be considered in practical analyses as uniformly distributed networks with adequately good approximation. The simplicity in analyzing a multielement network in terms of an "equivalent" uniformly-distributed network is borne out by a comparison of the solutions in appendix II with appendix I.

However, in lumped networks—and most apparatus is best represented by lumped networks—the characteristics of the higher harmonics differ from those determined from the uniformly distributed network. On the other hand, the higher the harmonic the less in general is the importance it assumes relative to the lower harmonics.

Effect of Dissymmetry in Networks

Dissymmetry in networks has a very marked effect in complicating the mathematical solution. Appendix III gives analyses for dissymmetrical three-mesh networks and illustrates the extent the equations become complex and cumbersome.

A comparison between symmetrical and dissymmetrical networks is best approached from specific consideration of the response, as in the three-mesh networks of figure 14. The comparison of the three networks is based on a total self-inductance, a total ground capacitance, and a series capacitance, each of which is equal for the three networks. The following are the equations of the voltages, where time t is in microseconds:

Symmetrical network, figure 14*A:*

$$E_{1G}=0.667-0.375\cos 0.035t-0.075\cos 0.049t$$

$$E_{2G}=0.333-0.375\cos 0.035t+0.075\cos 0.049t$$

Dissymmetrical network, figure 14*B:*

$$E_{1G}=0.86-0.19\cos 0.0324t-0.37\cos 0.070t$$

$$E_{2G}=0.57-0.54\cos 0.0324t+0.01\cos 0.070t$$

Network with mutual inductances, figure 14*C:*

$$E_{1G}=0.68-0.375\cos 0.039t-0.095\cos 0.064t$$

$$E_{2G}=0.32-0.375\cos 0.039t+0.095\cos 0.064t$$

where $M_{12}=M_{23}=0.4L$ and $M_{13}=0.2L$.

The principles discussed for symmetrical networks apply equally to the dissymmetrical networks. The amplitudes and periods are likewise determined from the initial distribution and the steady state, and from the distribution of the space waves (see equations above) in relation to the network (figure 14). Thus the fundamental periods for the dissymmetrical and the symmetrical networks are found closely alike for the reason that the product of the inductance and capacitance elements, which determine the period, remains substantially unchanged. The dissymmetry of the network B is accompanied by a corresponding distortion or skewing in the distribution of the fundamental space wave, as it readily can be noted from the equations above. The space wave of the second harmonic is concentrated largely across the two meshes at the line end; naturally the period is practically established from the circuit elements in these two meshes.
